CONTRIBUTORS

TO

VOLUME SEVENTY-TWO.

R. Abrahams, M.D., of New York.
Albert Abrams, M.D., of San Francisco.
Charles Lewis Allen, M.D., of Washington, D. C.
Royal W. Amidon, M.D., of New York.
Willis S. Anderson, M.D., of Detroit, Mich.
J. A. Bach, M.D., of Milwaukee, Wis.
Gorham Bacon, M.D., of New York.
Wesley B. Bailey, M.D., of Pekin, Ill.
L. Grant Baldwin, M.D., of New York.
G. H. Balleray, M.D., of Newark, N J.
P. V. Ballou, M.D., of Rowena, Ky.
William C. Bane, M.D., of Denver, Col.
L. Bolton Bangs, M.D., of New York.
Carl Beck, M.D., of New York.
A. L. Benedict, M.D., of Buffalo, N. Y.
Herman M. Biggs, M.D., of New York.
Albert E. Blackburn, M.D., of Philadelphia.
I. N. Bloom, M.D., of Louisville, Ky.
Henry P. Bowditch, M.D., of Boston.
Samuel M. Brickner, M.D., of New York.
Harlow Brooks, M.D., of New York.
Everett J. Brown, M.D., of Decatur, Ill.
W. F. Brunner, M.D., of Marine Hospital Service.
Arthur Conklin Brush, M.D., of Brooklyn, N. Y.
E. F. Brush, M.D., of New York.
Joseph D. Bryant, M.D., of New York.
J. N. Buckham, M.D., of Flint, Mich.
J. H. Burch, M.D., of Baldwinsville, N. Y.
James Hawley Burtenshaw, M.D., of New York.
F. C. Busch, M.D., of Buffalo, N. Y.
Glentworth R. Butler, M.D., of Brooklyn, N. Y.
W. K. Butler, M.D., of Washington, D. C.
H. R. Carter, M.D., Marine Hospital Service.
A. Morgan Cartledge, M.D., of Louisville, Ky.
E. C. Chamberlin, M.D., of New York.
George L. Chapman, M.D., of Chicago.
Palmer C. Cole, M.D., of New York.
George L. Cole, M.D., of Los Angeles, Cal.
Henry C. Coe, M.D., of New York.
Joseph Collins, M.D., of New York.
W. L. Coplin, M.D., of Philadelphia.
Edwin B. Cragin, M.D., of New York.
T. D. Crothers, M.D., of Hartford, Conn.
J. C. Da Costa, Jr., M.D., of Philadelphia.
Charles L. Dana, M.D., of New York.
Waller H. Dade, M.D., of Chicago.
E. P. Davis, M.D., of Philadelphia.
D. Bryson Delavan, M.D., of New York.
I. B. Diamond, M.D., of Houston, Tex.
George Dock, M.D., of Ann Arbor, Mich.
Fay M. Dunlap, M.D., of Bloomington, Ill.
Max Einhorn, M.D., of New York.
Henry L. Elsner, M.D., of Syracuse, N. Y.
J. H. Emerson, M.D., of New York.
Rosa Engelmann, M.D., of Chicago.
Henry B. Favill, M.D., of Chicago.
William Flitcroft, M.D., of Paterson, N. J.
Edward M. Foote, M.D., of New York.
George Ryerson Fowler, M.D., of Brooklyn, N.Y.
Melvin M. Franklin, M.D., of New York.
M. Howard Fussell, M.D., of Philadelphia.
A. Ernest Gallant, M.D., of New York.
H. J. Garrigues, M.D., of New York.
C. P. Gildersleeve, M.D., of Brooklyn, N. Y.
Herbert R. Goodrich, M.D., of Philadelphia.
J. Riddle Goffe, M.D., of New York.
M. M. Grady, M.D., of New York.
Egbert H. Grandin, M.D., of New York.
Allen McLane Hamilton, M.D., of New York.
Charles S. Hamilton, M.D., of Columbus, Ohio.
Hobart Amory Hare, M.D., of Philadelphia.
T. A. Harris, M.D., of Parkersburg, W. Va.
George C. Harlan, M.D., of Philadelphia.
Frank Hartley, M.D., of New York.
L. J. Harvey, M.D., of Griggsville, Ill.
Knut Hoegh, M.D., of Minneapolis, Minn.
Charles A. Holder, M.D., of Philadelphia.
George Homan, M.D., of St. Louis.
George T. Howland, M.D., of Washington, D. C.
Arthur M. Jacobus, M.D., of New York.
Jacob R. Johns, M.D., of Philadelphia.

Levi B. Johnson, M.D., of Muscatine, Ia.
Wallace Johnson, of Washington, D. C.
Jas. C. Johnston, M.D., of New York.
Joseph A. Kenefick, M.D., of New York.
H. A. Kilbourne, M.D., of U. S. Army.
Jas. P. Kimball, M.D., of U. S. Army.
Herbert Maxon King, M.D., of Grand Rapids, Mich.
Charles H. Knight, M.D., of New York.
D. L. Lainé, M.D., of Philadelphia.
John A. Lichty, M.D., of Clifton Springs, N. Y.
J. C. Lightfoot, M.D., of Alvaton, Ky.
R. P. Lincoln, M.D., of New York.
Frank E. Lock, M.D., of Buffalo, N. Y.
Eli H. Long, M.D., of Buffalo, N. Y.
M. D. Macdaniel, M.D., of New York.
M. L. Maduro, M.D., of New York.
W. F. Martin, M.D., of Colorado Springs, Col.
Claudius Henry Mastin, M.D., of Mobile, Ala.
Joseph M. Mathews, M.D., of Louisville, Ky.
Emil Mayer, M.D., of New York.
James H. McCall, M.D., of Huntingdon, Tenn.
S. J. McNamara, M.D., of Brooklyn.
A. Dan Morgan, M.D., of Witt's Mills, S. C.
Robert T. Morris, M.D., of New York.
J. B. Nichols, M.D., of Washington, D. C.
F. H. Nicolai, M.D., of Milan, Italy.
N. W. Noble, M.D., of Rochester, N. Y.
W. P. Northrup, M.D., of New York.
F. G. Novy, M.D., of Ann Arbor, Mich.
Seymour Oppenheimer, M.D., of New York.
Lambert Ott, M.D., of Philadelphia.
R. C. M. Page, M.D., of New York.
Thomas D. Parke, M.D., of Birmingham, Ala.
Isaac L. Peebles, M.D., of Hattiesburg, Miss.
Howell T. Pershing, M.D., of Denver, Col.
Frederick Peterson, M.D., of New York.
W. M. Pirt, M.D., of Barrie, Ontario, Canada.
Henry I. Raymond, M.D., of U. S. Army.
R. Harvey Reed, M.D., of Rock Springs, Wyo.
Julius Rosenberg, M.D., of New York.
E. Wood Ruggles, M.D., of Berlin, Germany.
B. Sachs, M.D., of New York.
Robert Sattler, M.D., of Cincinnati, Ohio.
H. A. Sifton, M.D., of Milwaukee, Wis.
W. Kelly Simpson, M.D., of New York.
Ellet Orrin Sisson, M.D., of Keokuk, Ia.
Fred. P. Solly, M.D., of New York.
Raymond Spear, M.D., of U. S. Navy.
W. G. Spiller, M.D., of Philadelphia.
George M. Sternberg, M.D., of U. S. Army.
Charles F. Stokes, M.D., of U. S. Navy.
Heinrich Stern, M.D., of New York.
Dudley Tait, M.D., of San Francisco.
John Madison Taylor, M.D., of Philadelphia.
Jerome B. Thomas, Jr., M.D., of Brooklyn, N. Y.
A. O. Trebeck, M.D., of Charlottesville, Va.
J. S. Triplett, M.D., of Harrisonville, Mo.
Frank Van Fleet, M.D., of New York.

VOL. LXXII. NEW YORK, SATURDAY, JANUARY 1, 1898. NO. 1.

ORIGINAL ARTICLES.

HYSTERIA IN CHILDHOOD AND YOUTH.

BY JOHN MADISON TAYLOR, M.D.,
OF PHILADELPHIA;
PROFESSOR OF DISEASES OF CHILDREN IN THE PHILADELPHIA POLYCLINIC; NEUROLOGIST TO THE HOWARD HOSPITAL; ASSISTANT PHYSICIAN TO THE CHILDRENS' HOSPITAL.

THE tendency during late years has been to make the diagnosis of hysteria much less rashly than of old. The time was, and quite recently, when a large number of puzzling functional affections were called hysteria, and treated as such. Increasing knowledge of the disorder is correcting this unfortunate mistake. True hysteria frequently occurs among children, in whom it is sometimes seen in a very graphic form, in boys as well as in girls, although twice as frequently in the latter. It increases steadily in frequency of occurrence from the third to the thirteenth year, and no age is exempt. The popular idea of this affection is that it is a mere feigning of disease, though hysteria, while simulating many disorders, is never a true imitation of any. It is a psychosis with clearly defined stigmata physical and psychic. Hysteria may be described, then, as a functional disturbance of the nervous system due to no known structural lesion, manifested by paralyses, convulsions, psychic, and sensory disturbances, and impairment of vision. The early recognition of all the neuroses of childhood is peculiarly important. This is epecially true of hysteria, which, if unchecked, seriously modifies character growth and psychic development, as well as obscuring the sequelæ of acute diseases.

In almost no other disorder do we see the influence of remote causes so admirably illustrated as in the hysteria of children. A neurotic ancestry of howsoever wide a variety may be manifested in the child in this form. It is rare, if not impossible, for children to be thus affected unless there is a clear history of neuropathic ancestry, along with debilitating conditions or emotional strain. It readily happens, too, that a powerful example may produce a hysteric outbreak in a well-balanced child. The influence of environment is a most potent factor in the production of hysteria. Exciting causes are: exhausting conditions, depressed health from acute diseases, injuries, abusive treatment at the hands of others, overwrought emotionality, and objectionable education generally, especially in religious matters. A very important study for the general practitioner is to search closely into the hereditary and other causes of all the neuroses in children, and it is also a very essential part of his duty. Whenever there is recognized ancestral alcoholism, insanity, or "marked peculiarities," the children must be doubly watched and guarded.

Hysteric symptoms are frequently seen during convalescence from infectious and other acute diseases. Imitative paralysis, contracture, tremor, and persistent local pain or tenderness are likely to follow various injuries, even very trifling ones. Vexations, disappointments, fright, shame, and, above all, religious excitement, are often potent factors in the production of psychic disturbances. An early encouragement of religious thoughts and training, especially of a kind which cultivates emotional exaltation, is powerful for harm in this direction. Perhaps the very worst influence of all, because more constantly present, is unwise, especially careless, home influences, lacking in systematic and watchful control, encouraging selfishness and minor deceptions deemed necessary by the child to secure what is coveted. Lax regulations as to duty and the higher moral faculties is the atmosphere most congenial to the growth of hysteria and even worse things. However, it must not be inferred that hysteria is solely the outcome of individual blameworthiness, nor is it always the result of lax moral conditions; for, on the other hand, puritanic severity is capable of working a large measure of harm. Disorders of the generative organs, especially those resulting from masturbation, are important causative agents, about which much might be said, especially as parents are singularly unwilling or unable to control habits of the kind mentioned.

By far the most important element in hysteria is the mental phenomena, which are exceedingly varied and complex, and, to a trained observer, capable of clear differentiation, and yet, when superficially studied, appear a mere mass of mental disturbances, imitative procedures, pretense, and deception. It must first be recognized that hysteria is not a simple feature of degeneracy, but a condition which may be acquired by children of unimpeachable parentage and otherwise excellent health. The child subject to hysteria is markedly impressionable, with a great tendency to accept and act upon suggestion. There

is a dissociation of the higher mental faculties, as of volition and cerebration, from lower emotional and impulsive states. The actions of a hysteric child during the paroxysm result from morbid concepts of associations of ideas, which permit the organic activities to exhibit characteristic irregularities. The key-note to the whole situation is suggestion, both in the production of the psychosis and the emancipation of the sufferer. Morbid suggestion from without or from within, one or the other, or both, produces the malady and encourages its continuance; and wise, forceful suggestion from without will affect a cure, especially if accompanied by well-chosen auxiliary measures systematically applied.

The paroxysm of hysteria consists of certain definite steps or procedures which continue from prodromal states with regular gradations to a systematic culmination, or they may be checked here or there, producing even more extraordinary features.

The paroxysm or hysteric fit has acquired the reputation of being the most important manifestation of the disorder, because it is the most conspicuous. It may, however, be absent or only rarely observed, or, again, but atypically exhibited. The more severe hysteric paroxysm has received the misleading name of "hystero-epilepsy," and is extremely rare, and when it does occur is difficult to differentiate from an epileptic attack. Nevertheless, it is hysteria, and has nothing in common with epilepsy. A better term, as proposed by Lloyd, is "hysteria major," just as in epilepsy we distinguish between the larger and lesser epilepsy (or *grand* and *petit mal*).

The hysteric paroxysm usually begins with certain antecedent features, mostly changes in the mental state, a shifting of the mood from its normal plane. There is never absolute unconsciousness. The exciting cause may or may not be apparent; if not, the point of departure of the fit may be some auto-suggestion.

The fit follows close upon an aura, which may be either sensory or motor. It may begin abruptly, or be preceded by alternate laughing or crying. It usually begins with a subjective feeling, as of a lump rising in the throat which is accompanied by a sense of suffocation. Another form of aura consists of loud noises, throbbing or beating sounds in the ears; still another is violent headache, a boring or piercing pain, as of a nail driven into the head (clavus hystericus). At other times there is dimness of vision, or alarming dizziness. Again, there may be sensations connected with the ovaries or testicles. The fit proper is usually divided into periods. The first or convulsive period resembles epilepsy, but is in no sense identical with it. The patient sinks down, or falls prone upon the back, with the limbs extended and rigid, but with the fingers and toes flexed; the eyes are usually rolled slowly from right to left, or crossed; the jaws are firmly clenched; the breathing becomes slow and labored, and later hurried, the face flushed or bluish, the neck turgid; the cardiac action becomes more rapid and forcible, and consciousness is blunted, or even almost, but never entirely, lost. Sensation is much obtunded, and abolished in some portions of the body. Soon clonic movements succeed—a tremor affecting the muscles of the trunk, extremities, and face. This alternates with electric-like startings, during which the patient may fling himself furiously about, or actually out of bed. Presently this stage ends with sighs, and is followed by a short sleep.

The next stage is one of dramatic movements, not so commonly seen here as in Europe. These may appear by themselves, and explain some otherwise puzzling conditions. The most common form is a complete opisthotonos, tonic spasm of the muscles of the back, a bowing of the lumbar curve until the child rests only upon head and heels. This may alternate with, or be replaced by, a variety of quaint attitudes and movements, some of which simulate purposive acts, and others are merely automatic. The final or closing period of the convulsive attack is one of delirium. This is usually an expression of the dominating mental attitude, and likely to be reproduced in each succeeding fit. It usually expresses some condition of fear or sadness, manifested by tears and sobs, and more or less incoherent appealings or pleadings. The attack is not always complete, one period may be exaggerated and the others left out. Especially in children, certain acts may be habitually performed, or changed by suggestion until the combinations are most extraordinary.

A series of apparently purposive movements, or merely automatic acts, may originate in one individual, and be so powerfully suggestive to others that they unconsciously imitate them, and thus a widespread contagion occurs in religious communities and schools, such as gave rise to the dancing manias of the Middle Ages. Somnambulism should be mentioned as having points of contact with the hysteric state. A lethargy, also, sometimes follows the paroxysm. Catalepsy, another psychosis strongly resembling hysteria, may be observed during or after the hysteric fit. The duration of a paroxysm may be but a few minutes, and then, with intervals of rest, be succeeded by others, as many as two hundred attacks having occurred within twenty-four hours in a case recorded by Sachs; or it may last longer, as in a case observed by me, in which the attack con-

tinued the greater part of two hours. Those which occur fragmentarily, or present considerable variety in their manifestations, may continue, with almost no intermission, day in and day out, as in the epidemic which occurred in the Church Home of this city while I was on duty there.

The hysteric paroxysm, as has been said, is not the most important symptom of hysteria. The permanent markings (stigmata) of hysteria have to do with changes in sensation, motility, the activities of the viscera, the mind, and nutrition. Alterations in sensibility are nearly always present. Hyperesthesia and local tendernesses are common, as in the well-known hysterogenous zones. These zones and areas of exalted sensation, over which, if pressure be made, pain is produced, and some one or other of the more graphic motor manifestations are elicited; the most common of these are over the ovaries and spine. In boys the testicles are sometimes hypersensitive. Pressure over these zones may give rise to a convulsion, or, again, may cause them to stop. A hysteric pain caused by an old injury may act as a hysterogenous zone, especially in one of the joints, as the hip or knee.

Disturbances or alterations of sensation are characteristic of hysteria. Anesthesia, more or less complete, is nearly always present in the hysteric subject, who may often be ignorant of its presence. Sometimes this is only of one side of the body, divided with great exactness in the middle line from head to heel (hemianesthesia); and sometimes occurs in irregularly distributed areas (disseminated anesthesia): or, again, is distinctly localized in one arm or one leg (segmental anesthesia). This last may be accompanied by motor impairment (palsy) of the part. The areas of anesthesia, when pricked, do not readily bleed (ischemia). The organs of special sense are often disturbed in hemianesthesia, and always upon the affected side. Of these the most important are the eyes; there may be a concentric narrowing of the visual field, or an alteration in the color fields (amblyopia or color-scotoma). There may be deafness of one side, or impairment of smell or taste. The changes in the color field (when characteristic) are one of the most certain points for differential diagnosis.

The disturbances of motility in hysteria are either loss of function (paralysis), or perversion of function (contraction and tremor). These symptoms are very apt to appear by themselves. The paralyses of hysteria simulate those due to central nervous disease in their distribution, but not in their clinical history. They may be named in the order of frequency with which they occur in children, *viz.:* paraplegia, monoplegia, and hemiplegia. The paralysis of motion is commonly, but not always, accompanied by paralysis of sensation. The onset is usually sudden, and in form may be flaccid or spastic. The immediate cause is usually some emotional perturbation, which may be psychic or traumatic. The contractures in hysteria may be either partial or complete, a local stiffening, or a spasm. These contractures may persist for years, though not always constant, and sometimes returning upon slight excitation; they may remain in the same place, or pass from one part to another. Tremor is rare in children; loss of voice is not common, neither is increased rapidity of respiration. Hysteric vomiting, also rare in the young, is a very serious matter when it does occur, imperiling health, or even life. Its character is *sui generis*, a mere regurgitation, due to a spasm of the esophagus. The intestine is sometimes paralyzed in hysteria, producing an immense bloating, with noisy belching, which is usually concomitant with a condition of emotional excitement.

Hysteria is a psychosis, a profound disorder of functional activities, of almost universal distribution, but due to no known demonstrable lesion. By some change in mechanism, an entire half of the brain is temporarily invalided, which alone can explain the complete hemianesthesia. The possibility of transferring this anesthesia from one side to the other would show the two halves of the brain to be in sympathy, one with the other. The cortical inhibition is lessened, leaving the lower centers unchecked. Recent views upon the mobility of the neuron points the way to a clearer understanding of hysteric states, but as yet scarcely explains the accompanying phenomena. The hysteric child evidences a marked vulnerability to certain perturbing influences, is always susceptible to psychic changes and functional disturbance. The manifestations of the disease may disappear during many years and yet readily recur under the influence of slight morbid agencies or changes in condition, or emotional irritation.

The treatment of hysteria in children or in adults is always complicated by the fact that the causes which produce it have so much to do with environment. It is difficult, almost impossible, to effect a cure unless the unfavorable environment be changed. It is easy to point out how a case may be benefited or cured, but not so easy to enforce the measures with sufficient thoroughness to produce a satisfactory result. The most important point in treatment, to be always insisted upon, is a complete separation of the child from its parents or previous caretakers during a considerable period of time. The physician finds himself in a very difficult situation, and will

usually be compelled to compromise. Indeed, it may sometimes be wiser to do this, and then gradually lead up to other measures more and more efficient and complete. The first part of the treatment should consist of the systematic application of measures directed to the improvement of general health, which may not seem obviously much impaired. An essential factor in the production of a cure is a properly qualified nurse, or (in rare instances), a wise and patient member of the family who can be taught to exercise the necessary control. The next most important element in the treatment is moral training, a complete remodeling of the point of view of duties to self and others.

It is of the greatest importance for physicians to realize that drugs are of no value whatsoever in the treatment of the psychosis known as hysteria. Judicious reasoning, frank conversation of an educational kind, and vigorous suggestions, with sometimes the added pomp and circumstance of the proper place and conditions, are powerful agents for good. Thus, a steady repetition of suggestion, with judicious and thorough detail, by a nurse or attendant trained to this end, is of great efficacy. As soon as the more severe symptoms are overcome and the child restored to uniform good health, proper educational measures must be steadily pursued. Remedial measures, directed to the removal of functional disturbances, for instance, hydrotherapy, electricity, especially the static form, massage, and regulated exercises, are of direct value. Strong faradic applications help to overcome hysteric paralyses, particularly in conjunction with encouraging words. The manner assumed by the physician exerts the utmost influence for good or evil. A frank, candid exposition of the patient's need should be clearly given. The medical man should be recognized by the patient as most kindly disposed, encouraging, and yet relentlessly firm.

For the sensory disturbances, the cold douche, or alternate use of hot and cold water, or the employment of some of the more picturesque devices, such as metalotherapy, may prove beneficial. Hypnosis will control a certain proportion of phenomena, and is rather easy to produce in children who, at best, are very impressionable, but is little better than repeated, direct suggestion at the hands of a physician whom the child has learned to respect and esteem. To overcome a paroxysm or convulsion the following measure may prove efficient: ice water dashed repeatedly over the face or back, or trickled steadily upon one point, as from a small hose or watering-pot; pieces of ice rubbed here or there on the back or chest, and lastly, inhalations of ammonia or nitrite of amyl.

THE OPERATIVE TREATMENT OF PTOSIS.[1]

By FRANK VAN FLEET, M.D.,
of New York.

Ptosis is a condition characterized by a drooping of the upper lid. It may be unilateral or bilateral, partial or complete, congenital or acquired. The congenital variety is generally bilateral, although it may be of varying degree on either side. In one of the cases in which I operated ptosis was apparent only on one side, but when corrected the contrast made it evident that the same condition, in lesser degree, existed in the other eye.

It is supposed that congenital ptosis is due to a lack of development of the levator palpebræ superioris muscle, although it is possible that it is the result of a malposition of the muscle, or to an anomalous distribution of the nerves. It causes a most characteristic appearance on the part of the affected individual. The drooping upper lid narrows the palpebral orifice in varying degree, depending upon the amount of ptosis present. The head is thrown back, and the eyeball rotated downward so as to bring the pupil on a line with the narrowed opening between the upper and the lower lids. While the downward rotation of the eye is generally due to this cause, it may result from a faulty development, or maladjustment of the superior recti muscles, a not unusual accompaniment, and one which must receive consideration in operative procedures directed to the correction of the ptosis.

In the three cases of congenital ptosis in which I have operated this complication was not present. In this affection there is also a wrinkling of the forehead due to the efforts of the occipitofrontalis muscle to assist in the elevation of the upper lids.

Acquired ptosis may result from syphilis (or any constitutional trouble which produces paralysis of the third nerve), traumatism, or diseases of the conjunctiva. A cause I had never heard of until it was mentioned by the first patient upon whom I operated for this affection was the use of the Davy lamp in coal-mining. It may have been only a coincidence, but the patient himself was firmly convinced that it was the cause of his eye trouble, and furthermore he said that it was not an uncommon occurrence among miners in the Welsh collieries who use the Davy lamp. The case of this patient is as follows:

J. H. P., aged forty-six years, formerly a miner in South Wales, presented himself for treatment in July, 1896. He had marked ptosis in both eyes. Until his eighteenth year he had never observed anything peculiar about his eyes, but at that time noticed that his upper lids drooped. In the mine in which

[1] Presented before the New York Medico-Surgical Society, October 4, 1897, and the Section on Ophthalmology of the New York Academy of Medicine, November, 1897.

the patient was employed there were about 1000 men, and the occurrence of ptosis, he said, was not uncommon. In the bituminous mines, where the naked lamps were used, this affection did not occur. When the disease manifested itself, the only remedy was to seek other employment, or at least to stop using the Davy lamp. However, the patient continued to work until the ptosis was so nearly complete that to see straight ahead it became necessary to raise the eyelids with the fingers. Fig. 1 shows the condition some time before he was compelled to give up his work, and is an enlarged copy of a photograph taken in England many years ago. Fig. 2, a copy of a photograph taken by Dr. E. S. Thomson, formerly house surgeon at the Manhattan Eye and Ear Hospital, shows the appearance of the same patient about thirteen months after the operation.

FIG. 1.

Showing appearance of patient with ptosis.

I would like to remark that the cause, as given by my patient, is not recorded as one of the known causes of ptosis so far as I have been able to ascertain, and may have been imaginary on his part.

The treatment of ptosis due to affections of the third nerve, is generally satisfactory when directed toward the cause, whether it be syphilitic or traumatic. When the result of trachoma, or any congenital condition, in which the drooping of the lid remains after the causative disease is cured, the deformity may often be remedied by simply removing an elliptic piece of skin from the upper lid and stitching the edges together. When this does not suffice, and also when the ptosis is the result of deficient muscular development, more extensive operative procedures have been unsatisfactory until recently. The levator palpebræ superioris muscle, having its origin in the orbit, is attached to the lid at about the convex margin of the tarsal cartilage, and its action draws the lid not only upward but backward as well. In the absence of this muscle, operators have endeavored to make the occipitofrontalis, the anterior portion of which is intimately adherent to the skin, take its place. The results produced by the devices of Pagenstecher, DeWecker, and others are satisfactory for the time being, but the objection has been that they are not lasting. We have, however, in the operation devised by Panas, a method which is generally satisfactory as to results, both immediate and remote. To this operation there is but one objection, *viz.*, it is complicated and difficult to understand. In fact, I know of no other operation the description of which is so confusing as this. An excellent description of this procedure may be found in De Schweinitz's work, "Diseases of the Eye," and a somewhat shorter one in Roosa's book, "Treatise on the Diseases of the Eye." There are many modifications of this operation, and I have taken the liberty of adding another. Possibly my operation is a copy of one which is already in existence, but be that as it may, I have employed it in five cases in which the immediate and remote results have been entirely satisfactory. My operation (Fig. 3), as I have taken the liberty of calling it for the time being, differs from that of Panas (Fig. 4), inasmuch as the lines of incision

FIG. 2.

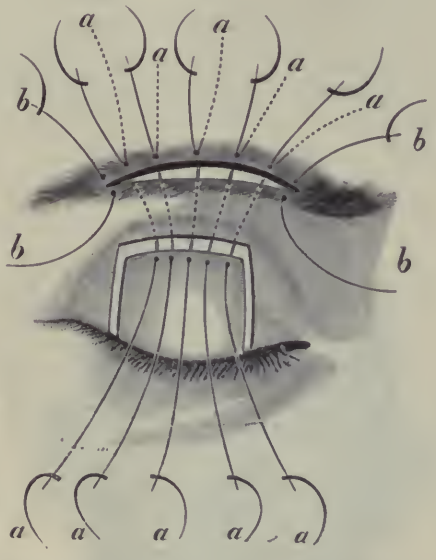
Showing the appearance of the same patient thirteen months after operation.

are straight and extend only through the integument. There is no danger of wounding deeper structures, and the flap, uniting by first intention to the upper edge of the incision in the brow, becomes a part of the skin controlled by the occipitofrontalis muscle

quite as much as it would had the incision extended down to the periosteum. A short description of this procedure is as follows:

The patient being anesthetized and the brow shaved, the face and forehead should be cleansed with a mercuric bichlorid wash. An assistant then inserts an ordinary horn shield under the lid, and with his free hand steadies the skin of the brow as directed by Panas. The operator makes an incision into the upper lid somewhat above the superior margin of the tarsal cartilage, commencing at the inner side and including the middle third of the lid. From the inner extremity of this incision another is made extending down to the ciliary border, and a third incision is made in like manner from the outer extremity of the first. The integument enclosed by these three incisions is dissected from the underlying tissues down to the ciliary border, and constitutes the flap. A final incision is made in the brow

FIG. 3.



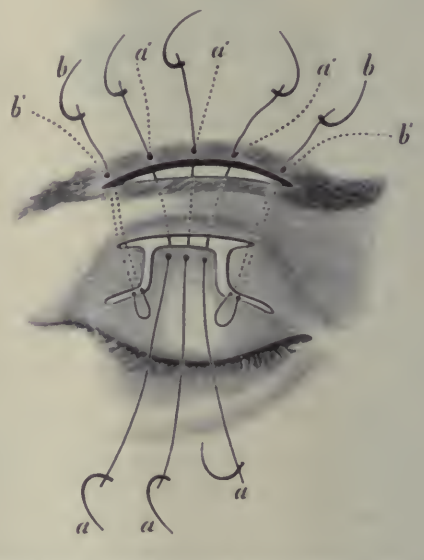
Van Fleet's modification of Panas' operation for ptosis.
a, *a*, sutures uniting flap to integument of brow.
b, *b*, sutures closing extremities of incision in brow.

parallel with the first, but slightly longer. The integument between the two is then undermined and forms the bridge. The parts are again carefully cleansed, the flap passed up under the bridge, and its upper margin stitched to the upper edge of the incision in the brow by means of five sutures. The outer and inner extremities of the final incision, *i.e.*, external and internal to the flap, are sutured, the wound dusted with iodoform, covered with bichlorid gauze, and bandaged. The latter is left in place two days, after which it is removed and daily reapplied during a week; when the stitches should be removed and the dressings discontinued. The epithelium of the flap becomes macerated and exfoliates, and the true skin unites with the under surface of the bridge, of which it becomes a part, or, perhaps disappears.

I believe it is well not to make the flap too narrow, but better, perhaps, to include even more than one-third of the lid. Its length should vary with the degree of ptosis to be overcome, always bearing in mind that it is better to have too great, rather than too little, resulting elevation of the lid, as the subsequent stretching of the skin tends to counteract the primary results.

I performed this operation upon a child, two years of age, for a physician in Brooklyn, who, after the operation, was alarmed because when the child slept the eye remained partly open. This continued a long time, perhaps six months, and the doctor feared the occurrence of keratitis, which we find following the inability to close the eye in facial palsy. In regard to such an accident the danger is nil; the patient may close the eye, and does so when occasion requires.

FIG. 4.



Panas' operation for ptosis (after de Schwienitz).
a, *a*, sutures uniting flap to integument of brow.
b, *b*, sutures advised by Panas to prevent possibility of ectropion resulting.

Another point to be remembered is that the shrinking of the bridge may cause a deformity, as shown in the left eye (Fig. 2) of the patient, to whose case I have previously referred. This has occurred in three of my five cases, and was easily remedied by freshening the edges of the wound and again stitching them together.

The two lateral sutures advised by Panas (Fig. 4, *b*, *b*,) I have not employed, but think that it may, perhaps, be well to do so in future cases; not because of the possibility of resulting ectropion, for in

this I do not believe, but because the two sutures mentioned serve to prevent stretching of the flap and consequent lessening of the good effect. Another question to be decided is whether the stitches which unite the flap to the upper margin of the incision in the brow should include the upper edge of the bridge. This latter has a tendency to curl, and if the upper edge be fixed, the tendency to cicatricial distortion will be lessened. There may be other points to be considered which will be suggested by individual operators.

NOTE.—Since writing the above I have been informed that Dr. J. Ascroft Tansley, of this city, has devised a similar operation. He has very kindly forwarded to me a reprint of an article describing his operation.[1] There is little similarity in these two operations except that they are both modifications of Panas', at least mine is, and I should imagine Dr. Tansley's to be so likewise.

EXPERIENCES WITH RETAINED INTUBATION TUBES AND ANTISTREPTOCOCCIC SERUM.

BY ROSA ENGELMANN, M.D.,
OF CHICAGO;
PROFESSOR OF PEDIATRICS IN THE POST-GRADUATE MEDICAL SCHOOL OF CHICAGO; CLINICAL INSTRUCTOR OF PEDIATRICS IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF ILLINOIS; CONSULTANT PHYSICIAN TO THE MARY THOMPSON HOSPITAL FOR WOMEN AND CHILDREN.

A MOST trying case of laryngeal diphtheria in which I performed intubation nineteen times within twenty-five days first called my attention to retained tubes as a complication of this procedure. Had O'Dwyer's brilliant and helpful article upon this subject then been published two lives might have been saved. Moreover, I would not have blamed myself for failing to do an early tracheotomy in the one case, although this operation proved futile in the second. At that time I had no knowledge of the short O'Dwyer tubes with larger head and lower, broader swell, nor of the tubes with built-up heads designed for cases of this kind.

The course of the disease and the *post-mortem* demonstration of subglottic ulcers, according to O'Dwyer, contraindicates tracheotomy. He says: "If extensive subglottic ulceration exists at the time the trachea is opened, the rapid healing which follows is very likely to produce a close cicatricial stricture, if not complete occlusion of this narrow portion of the larynx. Slow healing around a properly fitting tube is much less likely to be followed by contraction, and is the only safe method in these cases." His ingenious method of local astringent application by means of a medicated gelatinized intubation-tube might have been as efficacious in my cases as in his.

[1] *American Medical and Surgical Bulletin*, February 8, 1896.

CASE I.—James L., Italian, 2½ years old. I saw him for the first time on December 17, 1896, and the following history was elicited: Previous health good; father syphilitic, as learned from the family physician; child robust and well-developed; had been ill one day; primary laryngeal involvement; severe stenosis; temperature, 101° F.; pulse strong and full. At 5 A.M. I injected 5 c.c. of No. 6 antitoxin. At 11 A.M., No. 1 tube was inserted; it was expelled, after three-hours' retention, at 2 P.M., and we thought it to be too small. At 4 P.M., reintubated with No. 2 O'Dwyer tube; culture showed the presence of Löffler bacillus and staphylococcus pyogenes.

December 18th: Injected 5 c.c. of No. 6 antitoxin and 5 c.c. of antistreptococcic serum. After every antitoxin injection the temperature rose 2½° F., dropping the same number of degrees within eighteen hours. At 4 P.M. the tube was coughed up, with membrane, having remained in place twenty-four hours; 5 P.M., reintubated.

December 19th: At 9 A.M., seventeen hours later, tube expelled; 9.30 A.M., reintubated; 8.30 P.M., 11½ hours later, tube again coughed up; 9.30 P.M., reintubated.

December 20th: At 5.30 P.M., tube expelled, retained twenty hours; reintubated at 8 P.M.; pulse, 150; temperature, 102.8° F.; administered 5 c.c. No. 5 antitoxin.

December 21st: At 3 A.M. child suddenly became dyspneic, cyanosed, and convulsed in its effort to expel tube; some membrane appeared with the tube, the boy being strong enough to cough up the tube with, and ahead of, the membrane which doubtless had been occluding it; tube retained but 9½ hours; 4.30 A.M., replaced tube; retained eighteen hours; 10.30 P.M., tube expelled; retained 5½ hours.

December 22d: At 5 A.M., inserted a No. 3 tube, thinking that the edema had subsided to some extent and that pressure would hasten its disappearance. Five c.c. No. 4 antitoxin was given, 6500 units having been injected within six days. Later experience taught me that the antitoxin should have been more heroically and rapidly administered.

The diphtheria bacillus and staphylococcus were now associated with the streptococcus. Albumin appeared in the urine, remaining until the eleventh day of the disease, when it finally vanished. The No. 3 tube now remained *in situ* four days and five hours, then, on December 27th at 10 A.M., I removed it for cleansing, it having been worn ten days. It seemed to me about time for its permanent removal, but the boy was comfortable without it only three or four hours, respiratory difficulty increasing until twenty-one hours after its removal its reinsertion became imperative; temperature, 100.8° F.; pulse, 95; child taking nourishment well.

December 30th: At 3 P.M., or three days and five hours later, I extubated, fearing loss of resiliency and ulceration of the laryngeal walls; 6 P.M., reintubated for what seemed to be laryngeal and bronchial spasm. Whistling râles were heard over the entire chest;

temperature, 100.4° F.; pulse, 90; respirations embarrassed. A culture was taken which revealed the presence of the bacillus lanceolatus. To my mind this threatened pneumonia, for in quite a number of my cases this bacterial report had been significant.

December 31st: Temperature, 101.6° F.; pulse, 120 and irregular; physical examination revealed a bronchopneumonia.

January 1, 1897: Pallor; cyanosis; cold extremities; pulse 120, and regular; temperature, 100.8° F.

January 4th: At 3 A.M. the tube was again expelled; it had remained in place four days, 9½ hours; 4.30 A.M., tube replaced; 8.30 A.M., four hours later, it was again expelled; temperature, 99.2° F.; lungs clearing; 11 A.M., intubated; tube retained four hours, and was again coughed up; 4 P.M., reintubated; retained only three hours, and at 7 P.M. was again expelled. A No. 4 tube was now easily inserted, meeting absolutely no resistance. I was well aware of the danger of so large a tube, but apnea was threatened after each expulsion, and the father so dreaded this occurrence that he had learned to press back the tube which now rose with every expulsive effort.

January 5th: At 4.30 P.M. the boy strangled, and was so nearly asphyxiated that the father pulled out the tube. From its large size it was probably being impacted in the post-pharyngeal space. The larynx was undoubtedly so lacerated that it had become intolerant of the foreign body.

January 6th: At 12.30 A.M., ten hours later, reintubated with a No. 3 tube, although from the stretching of the parts I feared it might slip down into the trachea. A culture from the tube showed Löffler bacillus and staphylococcus; temperature, 100.4° F.; pulse, 120.

January 8th: At 12 M. the lungs appeared to be normal; temperature, 101° F.; pulse, 120; removed the tube after a retention of three days, 7½ hours; 2 P.M., replaced the tube as asphyxiation was imminent; no albumin in the urine; tracheotomy was advised, but refused by the parents.

January 9th: At 4.30 P.M., 5 c.c. of No. 4 antitoxin was injected. Up to this time 7500 units had been administered, but, as I now believe, not nearly enough, since upon this, the twenty-third day of the disease, the diphtheria bacillus still remained. The child had readily learned to drink inverted, but at each and every draught almost suffocated.

January 10th: Child playing.

January 11th: At 10.20 A.M., removed the tube to cleanse it; 10.25, gasping for breath; 10.30, dead before I could replace the tube or open the trachea.

Having gained the consent of the father, and in order to explain the cause of sudden death, we removed the larynx entire. Upon looking down past the vocal cords we could see absolute approximation of the subglottic walls, due to ulceration and loss of substance of the subglottic space. Another ulcer was seen in the right vestibule and still another on the posterior laryngeal wall. The laryngeal side of the epiglottis was about destroyed. Unfortunately the specimen was lost. Thus were the symptoms and unfortunate termination accounted for.

The futility of tracheotomy was proved in the following case:

CASE II.—Libbie M., aged two years and three months. She was a healthy, well-nourished girl, whom I had been treating for urticaria and some slight gastro-intestinal disturbance.

April 2, 1897: She had been ill thirty hours. Respiratory embarrassment was so rapidly progressive that intubation was at once performed. Before my arrival the child had received an unknown dose of antitoxin to which I added 5 c.c. of No. 6. The first culture showed staphylococcus; second culture, April 4th, showed the Löffler bacillus and the streptococcus pyogenes. Five c.c. of antitoxin and 10 c.c. of antistreptoccic serum were injected. The urine was normal; pulse, 120; temperature, 101.8° F.

April 5th: Morning temperature, 99.5° F.; pulse, 96; evening temperature, 98.2° F.; pulse, 100; respiration, 30, and unembarrassed; 11.30 P.M. Coughed up the No. 2 tube with some membrane; very cyanotic, and collapsed at 12.15 A.M., April 6th, when the tube was replaced.

Antitoxin administration doubtless caused local turgescence which, until its subsidence, was an added source of danger in the absence of a tube. Rapid membrane exfoliation obstructing the tube caused its expulsion at this most critical time. There were some peculiar erythematous patches around the site of the first injection.

April 6th: At 10 A.M. the temperature was 100.4° F.; pulse, 114; 5 c.c. of No. 4 antitoxin was injected.

April 7th: At 6.30 A.M. she coughed up the tube, which was completely filled with a semi-gelatinous, non-tenacious substance, probably dissolved membrane, for no shreds appeared later. At 7 A.M., when the tube was replaced, the child was almost asphyxiated and cold; rapid reaction; temperature, 101.8° F.; pulse, 150. At 6.30 P.M. the temperature was 103.6° F.; pulse, 150.

April 8th: 2 A.M. Giant urticaria involving entire body; face and eyelids enormously swollen; neck swollen even with angles of the jaw, so seriously affecting respiration that the tube was not fulfilling its purpose; there was doubtless pressure and edema above and below it. Dr. A. M. Thorpe, who had given me great assistance in the previous case, saw this child at my request, and reported no immediate danger. I did not see her until 11 A.M., when she was found delirious, scarlet, swollen beyond all recognition, and panting for breath; pulse and respiration too rapid to count; temperature, per rectum, 107° F. She was packed in sheets which were continually flooded with cold water, rubbed with ice, and ice applied to the head. Iced colonic flushings were likewise given. She sucked voraciously at the ice pellets placed in her mouth. Nitroglycerin, strychnin, and brandy were hypodermically administered.

Within twenty minutes the temperature was re-

duced to 101.2° F., and the pulse to 100. True, the respiration was still sighing and the body blue, but at 2 P.M. the thermometer registered 100° F., the respirations were 48, and the pulse 180, but regular. Such absolute loss of respiratory and circulatory control I hope never to see repeated. Infected antitoxin was unquestionably the cause of this trouble, for neither previous nor later doses had any such deleterious effect, profound toxemia evidently affecting the respiratory, thermogenic, and cardio-inhibitory centers. It seems clear that idiosyncrasy may be excluded.

April 9th: At 5 P.M. she coughed up the tube; great dyspnea and depression; 6 P.M., reintubated; general edema and urticaria disappearing.

April 10th: At 1 P.M., tube expelled with glairy mucus; no membrane; 3 P.M., intubated with No. 3 tube.

April 11th: 11 A.M., coughed this large tube into postnasal space, from whence it was extracted with difficulty by a neighboring physician who refused to reinsert it. The child was almost moribund when I arrived at 1 P.M. I temporarily inserted a No. 4 tube, wishing to reduce the laryngeal edema by pressure as well as by the length of the tube, in order to get above and below the edematous tissues which were interfering with respiration. When reaction was established, within two hours, tracheotomy *for the edema, not membrane*, was performed by Dr. Bayard Holmes; no membrane to be seen; some mucopurulent discharge from the tracheotomy tube. A culture made therefrom showed streptococcus, staphylococcus, and Löffler bacillus. The tracheotomy tube was clear most of the time, and the breathing comfortable.

April 12th: Sent to Cook County Hospital, where she died shortly afterward from sepsis and bronchopneumonia.

The next case may be classed with the above, but in one sense only. After what was supposed to be a final extubation and recovery there seems to have been a reinfection ten days later, necessitating another intubation.

Case III.—Jennie B., two years old; ill three days; tonsils and larynx involved; temperature, 100.2° F.; stenosis.

January 16th: Intubation. Given 5 c.c. No. 6 and 2 c.c. No. 5 antitoxin, and 5 c.c. antistreptococcic serum.

January 18th: Extubated in order to convince myself that the period of wearing the tube could be shortened; for in a series of six of my cases it had been worn respectively two and one-half days, three days, three days and three hours, four days, five days, and six days. That it could not be effected in this instance was conclusively demonstrated, since a reintubation was performed within half an hour; culture showed diphtheria bacillus.

January 19th: 10 A.M., temperature, 100° F.; breathing more labored than at the time of the first intubation, due to a complicating bronchitis; temporary anuria, but no albumin.

January 20th: Final removal of tube.

January 22nd: Father reports that the child is well; culture; Löffler bacillus.

January 24th: Culture showed Löffler bacillus, but very few and not characteristic.

January 26th: Child hoarse again and coughing.

January 27th: Bacillus lanceolatus was found, but no Löffler bacilli.

January 28th: Bronchopneumonia, and patches of membrane on the tonsils.

January 29th: Streptococcus and staphylococcus; severe stenosis requiring intubation; gave 5 c.c. No. 6 antitoxin.

February 1st: Sent to isolation hospital of Dr. F. W. Gillespie, to whom I am indebted for the subsequent detailed report.

Löffler bacillus again found, and 1500 units of antitoxin was injected. On February 2d, when the tube was removed, having been worn five days, pulse, temperature, and respiration were normal. The child was discharged on February 11th, having made an uninterrupted recovery.

Antistreptococcic serum was tentatively used in the previous and following cases, but because of the small dosage and the character of the infection, *viz.*, a mixed one, no conclusion can be adduced, nor would an expression of opinion be in order after so few observations. Nevertheless, the citation of a few cases in this connection will not lack interest:

Case IV.—Mary S.; thirty years old; no history of previous throat trouble; a strong, robust individual; ill twenty-four hours before coming under observation.

January 8, 1897: Pulse, 100; temperature, 101.8° F.; tonsils, soft palate, and uvula swollen, almost occluding interpalatal space, a typical picture of peritonsillar abscess. There were gray adherent patches on the tonsils; severe adenitis. A culture demonstrated the presence of the streptococcus and staphylococcus. Gave 10 c.c. antistreptococcic serum; urine negative before and after the injection; the temperature fell 2° F. within twenty-four hours. She was also given a bichlorid of mercury and iron mixture, and a gargle consisting of a twenty-per-cent. peroxid-of-hydrogen solution. Twenty-four hours after the injection there was the most remarkable subsidence of the local edema, redness, and some disappearance of the membrane. Within twenty-four hours, however, the swelling again appeared and there was so much distress that I lanced the tonsil, but did not find a clean staphylococcic abscess. There was much burrowing and many very small pockets of pus which no knife could reach. This condition was unquestionably of streptococcic origin. Another dose of 10 c.c. of antistreptococcic serum was injected. Results were as rapid and satisfactory as with the previous injection; cervical glandular enlargement also disappeared. Had I used a larger primary and secondary dose I believe lancing would have been obviated. I gave a third and final injection on the fifth day of the disease, when again some turgescence

had taken place. Within one week the patient was discharged cured, a very rapid recovery from what would have become a large peritonsillar abscess, ordinarily running a course of from two to three weeks.

The following is a case of scarlatina in which antistreptococcic serum was employed. The first throat culture showed the presence of the staphylococcus, the second, both staphylococcus and streptococcus.

CASE V.—Morris McK., six years old, excessively emaciated and asthenic; ill thirteen days with what had been called diphtheria. The tonsils, palate, and uvula were still covered with gray, adherent, foul smelling membrane. An adenitis was present; no albuminuria. The hands and feet were desquamating. Erythematous patches were located upon different parts of the trunk.

March 30, 1897: Twenty c.c. of antistreptococcic serum was injected. Temperature, 103.4° F.; pulse, 158; some bronchitis.

April 1st: Pulse, 156; temperature, 103.8° F. Only slight rise of temperature after the injection. Some inflammatory reaction and erythema at the point of injection which subsided within three days following the use of an ice bag, and a little later, application of ichthyol ointment.

April 2d: Patches exfoliating; adenitis decreasing; temperature, 101.2° F.; pulse, 120; bronchitis.

April 3d: Temperature, 102.6° F.; pulse, 120; bronchitis improving.

April 4th: Temperature, 101.8° F.; pulse, 120; injected 10 c.c. antistreptococcic serum; urine negative.

April 5th: Temperature, 98.2° F.; pulse, 100; patches disappearing; rapid desquamation. Tonics were administered, and the child now regained strength and flesh, and made what the parents called a marvelous recovery.

The following is a brief history of a coincident scarlatina and diphtheritic infection. The sudden typical onset of fever and rash was evidenced, but overlooking this the attending physician called the case one of diphtheria; I pronounced it scarlet fever. The report from the culture was Löffler bacillus and staphylococcus. Thus, we were both right and both wrong:

CASE VI.—Bessie S., eleven months old; tonsils, nares, and larynx involved; ill four days previous to observation. Culture showed staphylococcus and diphtheria bacillus. Gave 5 c.c. No. 6 antitoxin, and two doses of 20 c.c. antistreptococcic serum on alternate days. The attending physician reported a very rapid recovery from both diseases without complications. To prevent the latter might be a sufficient reason for the use of antistreptococcic serum in scarlet fever.

The difficulty of differentiating a simple streptococcic, scarlatinal, not necessarily streptococcic or diphtheritic throat, except by taking both clinical and cultural findings into consideration, is thus illustrated. In my first series of 100 cases of true diphtheria I was inclined to believe that the density and color of the membrane, excessive turgescence of the parts, even in the absence of membrane and low temperature, were characteristics of diphtheria. On the other hand, I have seen many cases with these peculiar attributes in which only staphylococci and streptococci could be demonstrated. Again, the infective agent of scarlatina has been supposed to be a variety of streptococcus, and many clinicians have asserted that the tonsils are its point of entrance into the body. In an article on "Scarlatina and the Streptococcus Infection," written in 1895, I suggested other infective atria, such as the gastro intestinal tract and skin. It is a curious fact that all throat cultures taken by me in cases of scarlatina during the past six months, and in five recent cases of scarlatina, show no other germ than the staphylococcus; whereas, I had expected in each and all of these cases to find the streptococcus. Much yet remains to be learned in regard to the genesis of throat lesions and their associated complications.

CLINICAL MEMORANDA.

A CASE OF HODGKIN'S DISEASE ASSOCIATED WITH MULTIPLE NEURITIS.

BY R. ABRAHAMS, M.D.,
OF NEW YORK;
DISTRICT PHYSICIAN TO MOUNT SINAI HOSPITAL.

M. L., Russian, male, single, aged thirty-five years. Family history unknown. During childhood he had smallpox as well as all the diseases peculiar to this period. His boyhood and youth were spent in idleness, both of mind and body. At the age of twenty, probably sooner, he began to masturbate. This habit continued until he was thirty years of age. About this time his fancy turned to thoughts of matrimony, but he soon relinquished the idea, as "by trial" he found himself incapable of performing the sexual act. His genital organs, however, were well developed. His second bad habit was the excessive use of alcoholic beverages. During six years he drank heavily and promiscuously—anything that was alcoholic. At the end of this time he began to experience pain in the lower extremities. The pain was dull, and at times shooting or lancinating, but always present. Some time after slight ataxia supervened, when he sought refuge in a hospital. At this institution he received both medicinal and electric treatment nearly a year, with neither real nor apparent amelioration of his symptoms. During his stay in the hospital alcohol was absolutely withheld.

At this time a small "fleshy lump" made its appearance on the right side of the head, joining the neck. The lump slowly but steadily increased in size. A few weeks after a second tumor appeared on the same side of the head. When the second swelling attained the size of

a horse-chestnut it stopped growing, while the first continued to increase until it reached the size of a small orange.

He consulted me during March, 1897. On examination the patient was found to be of medium size, with a mild lateral curvature of the spine (Fig. 2). Otherwise

FIG. 1.

Showing appearance of patient with Hodgkin's disease.

he was well built and well nourished. The heart, lungs, liver, spleen, and kidneys seemed to be normal. He had dyspepsia of moderate degree. He stoutly denied alcoholism, but admitted masturbation; never had any venereal disease. He complained of constant shooting and burning pain in the lower extremities. The pain was aggravated by pressure. Mild ataxia was present; total absence of patelar reflex on both sides; staggering on walking with closed eyes; feeling as if walking on sand, and, *upon suggestion*, he owned to the girdle sensation. It must be mentioned that the Argyll-Robertson pupil was absent; the sphincters were normal, and electric tests yielded negative results. The clinical picture, therefore, was suggestive of locomotor ataxia.

The man had scarcely been two weeks under observation when new features developed. The glands of the neck showed an appreciable increase in size. At the same time two glandular enlargements became visibly apparent at the upper borders of the parotid glands. In the course of two weeks more the axillary and mammary glands gave optical evidence of abnormal growth. A glandular, movable mass appeared over the sternal notch. It was also noticed that while these glands were increasing in size the abdomen also was growing larger, although repeated and careful examination did not reveal any alteration in the size of the internal organs. The rapidity with which the glands enlarged was very remarkable. Within six weeks the cervical glands presented one continuous mass, hanging down like a double chin; the mammary glands attained the size of large oranges. The two old enlargements on the back of the head shared in the general hypertrophy, so that they became double the original size. The accompanying figures fairly illustrate the condition.

The only subcutaneous lymphatic glands which escaped enlargement were the epitrochlear and inguinal. The constitutional disturbances accompanying the glandular phenomena were slow but progressive anemia and loss of appetite and muscular strength. At this stage, with a clinical diagnosis of leucocythemia, the blood was examined. Dr. F. S. Mandelbaum, Pathologist to Mt. Sinai Hospital, to whom I am indebted for the examination, reported May 19th as follows: "Your patient's blood shows 2,900,000 red and 4500 colorless corpuscles per c. m. The ratio, therefore, is 1 to 644, which comes within the normal limit. The percentage of hemoglobin is 60 per cent. (Fleischl.) The dried and stained preparations showed that the majority of white corpuscles were of the

FIG. 2.

Back view of same patient, showing to some extent the glandular enlargement.

ordinary neutrophile, polynuclear type. A few mononuclear forms were seen, but no lymphocytes or eosinophile cells were present. There was a moderate degree of poikilocytosis, but no nucleated red corpuscles were found."

About the first of June the patient began to complain of marked weakness in his forearms and legs. This terminated, within a day or two, in complete motor-paralysis of the extensor muscles of the forearms and legs. Sensation was undisturbed, and there was pain on pressure along the nerves. Within a few days the muscles grew flabby, showing a tendency to rapid degeneration. At the same time a mild delirium tremens developed, accompanied by a reluctant confession to a history of prolonged and profound alcoholism. The delirium was quite active during the night. During the day the patient's intellect was comparatively clear, although he never ceased picking snakes around his bed and bedding. Slight jaundice and bronchitis, difficult breathing, and loss of control over the bladder developed. Intestinal hemorrhages were frequent and marked after the patient took to bed. On the 10th of June he died of acute edema of the lungs; no autopsy.

The treatment was carried out with system and regularity. It consisted of the internal administration of strychnin, $\frac{1}{60}$-grain doses, gradually increasing to $\frac{1}{10}$-grain three times daily, and also increasing doses of the arseniate of soda. Alcohol was absolutely forbidden. Nourishing food and every obtainable comfort were secured for him, but all were of no avail.

Besides the interesting combination of multiple neuritis and Hodgkin's disease presented by this patient, the case emphasizes a valuable lesson in diagnosis. Strümpel and others regard the differential diagnosis between chronic alcoholic-neuritis and tabes dorsalis as not only important but quite difficult. The resemblance of this case to one of locomotor ataxia was only intensified by the absolute denial of a history of alcoholism, which was steadfastly maintained almost to the end. Other interesting features of the case are the utter failure of treatment and the rapid and fatal termination, justifying, indeed, the name given to Hodgkin's disease, namely, malignant lymphoma.

A CASE OF PURPURA RHEUMATICA.[1]

By WALLACE JOHNSON, M.D.,
OF WASHINGTON, D. C.

W. L., male, aged twelve years. The patient was anemic, not well developed, and complained of pain in the back and abdomen, and also in the left elbow and right knee. The joints were found to be slightly swollen, red, and painful on motion. The thermometer indicated a slight rise of temperature. The patient's mother stated that during the few days preceding the examination he had had pain in various joints and also abdominal pain, particularly at night. At night, when the pain was most severe, vomiting occurred. Sodium salicylate in 10-grain doses was ordered to be given every three hours.

The next day, October 1st, the location of the pain had changed from the joints previously affected to the opposite elbow and left ankle. The severe abdominal pain at night continued; temperature, 101° F.

October 6th: During the first few days of this month the location of the pain frequently changed from one joint to another, and at present has entirely disappeared. The abdominal pain previously referred to persisted, though only at night, and was still accompanied by vomiting. There was no rise of temperature after October 2d; the bowels acted daily. During the morning there was present a slight tenderness over the upper abdomen, which by evening disappeared. Owing to the regularly recurring attacks of colic, the blood was examined for malarial parasites, but none were found.

October 8th: A dose of calomel emptied the bowels of a large quantity of feces, which was examined for the presence of any intestinal parasite that might be the cause of the colic. A few eggs of the tricocephalus dispar were found; but as all authorities agree that this parasite has no clinical significance, its presence was not considered a causative factor of the colic.

October 9th: Patient felt well and did not have colic the previous night.

October 12th: Three days before, after unusual exertion, the patient's feet swelled, became painful, and that night another attack of vomiting and colic occurred. At the time the mother noticed an eruption, "like that of scarlet fever," over his hips, ankle, and knee-joints. This eruption soon faded, and left only a few purpuric spots over the joints mentioned; colic and vomiting persisted at night.

October 27th: The joint-pain was entirely overshadowed by the severity of the colic and vomiting; temperature normal.

October 28th: After the administration of calomel and castor-oil the patient had a large movement of the bowels in which some blood was observed; no colic on the preceding night.

November 1st: No colic since October 27th; profuse purpuric eruption was present over both legs and extended as high as the waist; a few spots over wrists and elbows; none on the upper part of the trunk.

November 8th: The pain did not recur until the night of November 6th; it lasted a few hours and was not accompanied by vomiting. The next day the ankles were swollen and painful, but this condition disappeared within twenty-four hours.

November 10th: Slight abdominal pain on the preceding night; a few new purpuric spots had appeared.

November 15th: A new outbreak of purpura was present over both legs. A careful examination of the heart by Dr. J. D. Thomas did not reveal the presence of any abnormality. During the last two attacks of colic a rise of temperature did not occur.

The course of the disease was characterized by an apparent division into three successive periods, separated by intervals of eight to ten days of comparative health. Each exacerbation was marked by attacks of colic accompanied or preceded by rheumatic pains in the joints and followed by a purpuric eruption. The three prominent symptoms apparently had some relation one to the other, and were evidently not affected by treatment. During the first attack the relief of the colic was coincident with active purgation; in the second, relief preceded purgation; and in the third, a carthartic was not given. Under

[1] A disease resembling a form of purpura observed by Henoch of Berlin, and sometimes called Henoch's disease.

these circumstances it seems likely that the end of an attack and the action of the calomel were but coincident, not interdependent. After the first each subsequent attack was seemingly due to over-exertion.

NEW INSTRUMENT.

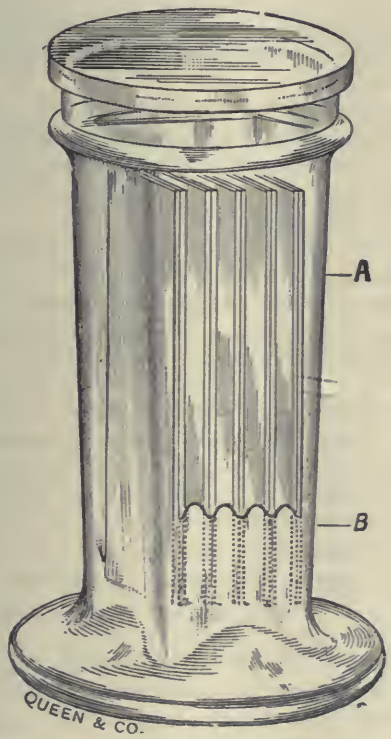
A NEW LABORATORY DISH.

By W. L. COPLIN, M.D.,
OF PHILADELPHIA;
PROFESSOR OF PATHOLOGY AND BACTERIOLOGY IN THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

IN the laboratory of the Jefferson Medical College we almost exclusively use for routine work the paraffin method of embedding. The blocks of tissue are infiltrated in the usual manner, and the sections cut with the Ryder, or Minot microtome. The student cuts his sections and fastens them on the slide by means of Ohlmacher's combined water-albumen method, in combination with certain improvements of the methods of Gaule and Mayer. These are then kept from twelve to twenty-four hours in the drying-oven at a temperature of 37° C., until all the water is evaporated, the paraffin and section having, during the evaporation of the water, straightened out perfectly. The slide is now gently warmed until the paraffin, which has a melting-point of 45° C., begins to melt when it is thrust into kerosene, which in ten minutes completes the removal of the paraffin. The excess of kerosene is wiped off, the slide washed with a few drops of alcohol and then placed in a dish of alcohol; from this dish of alcohol the staining is conducted as usual. If the tissue has been hardened in corrosive sublimate, it is necessary to carry the cemented section through diluted tincture of iodin to remove the mercuric salt; this is followed by washing in alcohol when the section is ready for staining. The stains are conveniently kept in large salt-mouthed bottles into which the slides are placed for staining, mordanting, dehydrating and clearing.

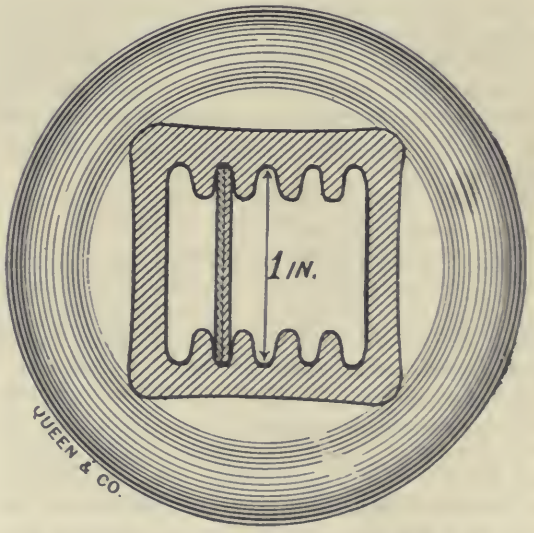
It is usual for the student to take from five to ten slides through the various solutions at one time, and in so doing he not uncommonly scratches the section off one slide by rubbing it against another. This difficulty arises no matter whether the method of Gaule, Suchanek's modification of Gaule's method, Gulland's modification of Gaule's method, or what is better, Heidenhain's water method be used. Even employing any of the collodion methods does not permit us to escape this danger. In order to overcome this, the writer sought very carefully through the dishes which have been designed by various workers, but failed to find anything which was ideally available. True, Ranvier has designed a rack upon which a number of slides may be supported, but this is entirely too cumbersome for general laboratory use, and besides involves a large amount of fluid, which makes it an expensive luxury. With these points in view, I have devised a dish which is expected to overcome some of the above difficulties.

FIG. 1.



This cut is about two-thirds of the exact size of the dish. At *A* can be seen ten slides, placed back to back, and passing down between the ribs at *B*. Since this figure was drawn the width of the base has been increased, so that the base is now the width indicated in Fig. 2.

FIG. 2.



This represents a transverse section of the dish at the point marked *B* in Fig. 1, viewed from above and showing the ribs and intervening grooves. The two arrows mark the position occupied by a slide one inch in width. Just to the left of the arrow is shown a transverse section of two slides placed back to back, as is usually done for staining.

The inside measurements of the dish are 3½ inches in height, 1 inch square at the bottom, 1⅜ inches square 3 inches from the bottom, and 1¼ inches in diameter at the top which is round, and closed by means of a ground, grooved, Stender cover which when in place makes the

dish air-tight. In order to render the dish stable, the base is the broadest and heaviest part, measuring nearly 2½ inches in diameter. Extending upward from the bottom on the inside and on two opposite sides, are eight ribs, four on each side, forming between them three grooves sufficiently wide to admit in each groove two slides of ordinary thickness. Two slides can also be placed in the outside groove, between the outside ribs on either side and the inside of the dish. This gives the dish for ordinary purposes convenient and not crowded accommodation for eight slides standing on end, or if the sections are small, and the slides thin, four slides may be placed outside of the ribs, two on each side, back to back, making ten in all.

An ordinary Stender dish requires about 120 cubic centimeters of fluid to immerse a slide sufficiently to cover a section cemented to its center. The above dish requires less than one-third of that amount to secure an equivalent degree of immersion. Of course, these dishes vary slightly in their capacity, as all pressed glassware will; such a variation, however, does not amount to more than from ten to fifteen cubic centimeters.

Where, for reasons of economy, or otherwise, it may be desirable to close the top of the dish by means of a cork or rubber stopper, the expense may be materially reduced. Wheh closed by means of a glass cover, as described above, and shown in the illustration, the cover and the dish will each bear the same number cut in the glass, so that the student working at his desk, may easily avoid mixing the covers which would not only be detrimental by mixing incompatible fluids, but as each lid can be ground only to fit the dish which accompanies it, exchanged lids would not fit tightly.

In order to facilitate cleaning and to avoid inaccessible corners, all the angles are rounded.

The advantages claimed for the dish are: (1) Convenience; a number of slides can be safely handled at one time. (2) Great economy in the use of reagents; not only is the amount used less than is required with the Stender dishes, but in case, as will not uncommonly occur with students, anything happens which ruins the contained fluid the loss will be materially less. (3) No other dish of the same height and the same capacity possesses equal solidity. (4) Contained fluids are prevented from evaporating by the tight-fitting top. This is not secured in the Naples dish.

I desire to express my appreciation of the assistance rendered by Messrs. Queen & Co. in securing working drawings from which the above cuts have been made, and the final successful production of the dish.

THERAPEUTIC NOTES.

Gelatin as a Hemostatic.—CARNOT (*Ther. Wochenschr.*, September 26, 1897) finds that of all the agents used to induce coagulation of the blood none equals gelatin. Its power of coagulability was shown by experiment some years ago, and even in small doses this is evident in hemorrhage from an exposed surface, such as the nose or the skin, where the temperature is below that of the melting-point of gelatin. In the organization of a blood-clot, the influence of the contained gelatin is for good, as it has a favorable nutritive effect upon the forming granulation-tissue.

Gelatin may be used in a five-to-ten-per-cent. solution in water, or, better, in normal salt solution. This preparation should be sterilized, on two successive days, at 100° C. during fifteen minutes. In several cases in which children were brought into the hospital bleeding from the nose, of several day's duration, Carnot was able to stop the hemorrhage at once by the injection into the nasal cavities of an ounce or two of this mixture, and the insertion into the nose of a tampon soaked in the same fluid.

The fluid must not be above the body temperature when brought into contact with the bleeding surface. In hemorrhage from the stomach or intestine, the remedy is useless, as the digestive action of the stomach destroys its virtue. In metrorrhagia, it is of incalculable value, if injected into the cavity of the uterus under aseptic precautions. Similar treatment serves to stop persistent rectal bleeding.

In surgical operations in situations in which hemorrhage is not easily controlled, the application of swabs of cotton soaked in the gelatin solution will stop the bleeding almost instantly. This is especially valuable in operations on the liver, kidney, etc.

To further coagulability of the blood in general, the gelatin solution may be introduced into the rectum, or injected subcutaneously. By the latter method a hemophiliac may be saved from a long hemorrhage and a beginning purpura hemorrhagica may be cut short.

The Hypodermic Administration of Quinin in Malaria.—DUNHAM (*Vir. Med. Semi-monthly*, November 12, 1897), who has had a great deal of experience with malaria, is an advocate of its treatment by means of the subcutaneous administration of quinin. It is recognized that the segmentation of the plasmodia occurs just before or at the time of the chill. A much smaller dose of quinin than is ordinarily required, if administered at this time, will quickly control the attack. It is in the case of patients who do not well tolerate the drug, or when it is desirable to cut short an attack, that the hypodermic method is especially valuable. The hydrochlorosulphate is the best salt for injection, as it has the strength of the sulphate, and its use in the manner indicated is not painful. In many cases, a 5-grain dose of this salt injected four hours before the expected paroxysm and the same quantity injected four hours after its occurrence, will at once check the disease, and completely cure it within four or five days. In some instances larger doses will be required. In cases of the estivo-autumnal form, it is advisable to begin treatment at once and to push it relentlessly, at the same giving the patient the benefit of the best hygienic surroundings. A relapse is even then likely to occur, and the cure must not be considered perfect until several weeks have passed without a recurrence of the disease.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, JANUARY 1, 1898.

THE DISPENSARY BILL.

THE text of the "Dispensary Bill" which it is proposed to introduce in the State Legislature this winter will be found on another page of this issue, incorporated in the final report of the Committee on Charity Abuses as presented to the Medical Society of the County of New York at its last monthly meeting. This measure is the result of mature and careful deliberation, and has the endorsement of the principal medical societies of the State through their representatives in joint committee.

The bill as presented differs materially from the one which passed the Legislature last winter but failed to receive the Governor's signature. The great improvement—for this measure is vastly better than the former—lies in the fact that too much "reform" is not attempted. It avoids the fatal mistake of the now famous Raines' law, inasmuch as impossibilities are not contemplated—no effort is made to define a "poor person," which was an organic error in the former bill.

The primary essential object that will be accomplished by the enactment of this law is the placing of the dispensary question upon the statute books, giving it, as it were, a legal status. Practical experience in its application will suggest from time to time such amendments as the exigencies of the future may necessitate. The admirable feature of the measure lies in its conservatism, which cannot fail to insure for it a united effort on the part of the profession to place it among the laws of the State.

The State Board of Charities, which is given power to grant and revoke licenses under which dispensaries are to be conducted, will be responsible for the administration of the law. It will not be necessary for the medical profession to do police duty as has been the case in the enforcement of the general medical law of the State—a law successful only through the efforts of the profession. The members of this Board will no longer be able to say "we lack power," for, possessing authority to make rules and regulations governing the conduct of dispensaries, and armed with the power to revoke licenses in aggravated cases, the members of the Board will have it in their hands to elevate the present defective dispensary system to a constructive instead of a destructive charity.

THE MEDICAL NEWS bespeaks for the bill the prompt and favorable consideration, not only of the Legislature but also of the Governor, and foresees in the wise administration of such a law prompt relief from a great social abuse.

THE FAITH-CURE AGAIN.

DURING the last two weeks two deaths have occurred, the immediate result of the nefarious practice known as the "faith cure." The child of a man in Camden, N. J., died of what we understand to have been diphtheria. Later the father and a certain "faith-cure" professor were summoned before the court on the ground that they had caused the death of the child. There is no necessity to go into the details of the hearing and the hopeless ignorance and superstition displayed, but it is gratifying to know that the jury, after being out a few minutes, returned a verdict that "the child came to her death through the criminal negligence of her father, the aforesaid professor being an accessory." Something of the same kind occurred at Baltimore, the particulars of which we do not happen to have at hand. It is mentioned in order to emphasize the pressing need of legislation against such preposterous, indeed, criminal practices.

From Pennsylvania comes the report that Christian Science has received a set-back in that State from

which it will find it most difficult, if not impossible, to recover. Through a judicial ruling recently made by Judge Pennypacker, permission for the incorporation of the creed which substitutes "metaphysical healing," as it is termed, for rational diagnosis and therapeutics, has been denied, and the practice of this ridiculously fatuous belief, if it may be called a belief, has been uncompromisingly declared as "against the law of the State."

Some of the points brought to light in this legal investigation as to the claims of the Christian Scientists appear both absurd and dangerous; absurd, because of the revelation they bring of the queer medieval mental perceptions prevalent among this sect; dangerous, on account of the immense risk to human life their application involves. Their teachings declare, for example, that "metaphysical healing" extends to such serious and fatal diseases as rheumatism, scrofula, cancer, smallpox, and consumption; in the latter disease, the *naïve* advice is given to "take up the leading points included, according to the individual's belief in the disease, show that it is not inherited, that inflammation, tubercles, hemorrhage, and decomposition are only beliefs, and these ills will disappear." Regarding luxations, they are equally hopeful, and in all seriousness "authenticated records" of the cure "through mental surgery alone of dislocated joints and spinal vertebræ" are offered for the Court's inspection. In the case of infants and children too young to understand the wonderful intricacies of the Christian Scientist's mind, the mental receptivity of the little one's elders transfers the cure through them to the child! The technic point of law upon which the ruling of the Court was based was obviously that which relates to the practice of medicine in Pennsylvania; and coming as it does so soon after the two lamentable instances of loss of life above referred to, the decision must be considered a timely piece of judicial action.

TREPHINING FOR HEMIPLEGIA AND NEWSPAPER NOTORIETY.

IN THE NEWS of last week we commented editorially on the Public Press and the Academy of Medicine anent the question of allowing reporters of the daily papers to be present at the meetings of the Academy and its Sections, and to make such report of the proceedings as they decided would startle or interest their readers. The fact that much surreptitious advertising, evading the letter of the code of ethics, while violating its spirit, is indulged in, is patent to the most unobservant. But the transgressor who thus attempts to bring his wares to the uncritical eye and gullible mind of the laity, is in nowise to be compared, in the matter of depravity, with him who gets the ear of the reporter in private and fills it with glowing statements of his own revolutionizing discoveries and brilliant achievements.

Such a flagrant example of the latter kind of advertising, not to speak of other reprehensibilities, has recently been perpetrated by a surgeon of this city, that we are constrained to call attention to it. As it involves not alone the ethical side of the question, but concerns as well, probably, a mistaken diagnosis and possibly an unwarranted procedure in the treatment of the patient, we shall content ourselves at this juncture with a recitation of the case, leaving for a future time, until the surgeon in question has had an opportunity to deny and disprove the report of statements attributed to him, a more personal consideration.

The facts of the case, so far as we have been able to learn them, are as follows: A man, fifty-six years old, was seized suddenly, without particular premonitory symptoms, save that of headache of several days' duration, with a sensation of numbness and unwieldiness of the right leg, and within a few minutes with a similar condition of the right upper extremity of the same side. The right half of the body rapidly became hemiplegic, and within a quarter of an hour the patient was comatose. He was seen immediately by a physician, who called a surgeon in consultation. The latter, on seeing him, advised that he be removed to a hospital and trepanned. And within four hours from the occurrence of the apoplexy the patient was trepanned over the left parietal region. With what object in view it seems difficult to conjecture.

Nothing abnormal was discovered, although an exploratory needle was carried into the brain in different areas, the lateral ventricle among them. A considerable quantity of cerebrospinal fluid, including that of the lateral ventricle, escaped. No blood, fluid or clotted, save that spilled in the operation, was found. The patient rallied, and after three or

four days began to recover consciousness in a way exactly parallelizing a goodly number of apoplectic patients whose lesion is a thrombosis or moderate rupture of the middle cerebral artery, even when they are not bled or given vasomotor equalizers and absolute rest, the sequelæ of the attack symptomatically being right hemoplegia and total aphasia. Then comes the startling information through the medium of the secular press that a new treatment, "Trephining for Apolexy," had been vouchsafed to afflicted humanity at the hands of a surgeon to —— Hospital. The symptoms of the patient's illness are given in detail, and then the surgeon is quoted as saying to the reporter, his remarks being in quotation marks as they are here: "I have given much thought to the subject for a long time." Alas, that such things should be! "And I had been waiting for just such a chance as this to put my theory into practice. I have proved now that ordinary apoplexy may be cured by trephining." The *naïvete* of this concluding remark, the hope that it holds out to sorrowing ones who see those immeasurably dear to them stricken with this alarming condition, is to them like the Balm of Gilead, and the genesis of the hopeful statement may have been founded on the belief that the hand which applied the balm so skilfully and efficaciously in this case might be asked to do it in another; yes, even in scores of others, until his megalomaniac claims shall be shown by sad experience to be an air bubble. But, to continue the reputed words of the surgeon, "I believe that this is the first time that trephining for an ordinary case of apoplexy has been resorted to." We concur in this belief, and we gratefully thank the surgeons, past and present, for their concurrence in establishing this most praiseworthy status. And if prayer or supplication is of avail to keep this so, we humbly offer it. That any man should be so bereft of the faculties constituting common sense or judgment as to believe for one moment that he can reach the seat of lesion without sacrificing the patient in a case whose features mirror absolutely the most typical case of cerebral apoplexy due to occlusion or rupture of the middle cerebral artery, surpasses human understanding.

"Any literature that I have read upon this subject does not refer to the treating of ordinary apoplexy in this manner, and I believe that I am a pioneer in this direction." And again we concur! No, a thousand times no. There is no literature on the subject, and so long as the rank and file of physicians are recruited from men and women endowed with sufficient gray matter to comprehend the rudiments of anatomy and physiology, and the underlying principles of pathology, so long as the geniuses of our profession do not outrage their endowments and the unknowing do not violate their trust, there never will be such a literature. He is a pioneer indeed; the pioneer who prepares the holocaust and brings grief to many. We are desirous of doing no man an injustice. We contend for the rights of the individual, and we believe in the supremacy of personal opinion. If the surgeon in this instance believed that he had to do with a supracortical hemorrhage, then operative interference was justified. But in a man fifty-six years old, whose urine was shown on examination to contain casts and albumin, who develops the symptoms of cerebral apoplexy without preceding trauma or evidences of local contagious disease, supracortical hemorrhage is so extremely rare that, in truth, careful deliberation on the part of those to whom his fate is entrusted and the counsel of those whose experience has been great along the lines of such disease is the smallest consideration that should be granted him.

We refrain from further comment on this matter for the time being, for we would gladly learn and convey to our readers that the words of the daily papers, apparently coming directly from the surgeon, were false, and that the case is one that must be ascribed to misplaced zeal or mistaken diagnosis.

ECHOES AND NEWS.

Medical Faculty of Paris.—The theses for the degree of Doctor of Medicine presented to the medical faculty of Paris during the year 1896-97 numbered 640.

A Statue to Pasteur.—A statue to the memory of Pasteur has been erected at Melun by the agriculturists and the veterinary surgeons of the Departments of Seine and Marne.

The Sale of Serum.—The authorities of Paris have discovered that, although there is a law which forbids it, certain chemists have been manufacturing and selling preparations of serum. It has not yet been ascertained whether, as in the case of tuberculin, any of these preparations are fraudulent.

A Healthy Locality.—Friendsville, a little village in the Pennsylvania mountains, is remarkable for the longevity of its inhabitants. The town contains 135 inhabitants, of whom 27 have passed the age of ninety.

Medical Men and Preliminary Imprisonment.—The Obstetrical and Gynecological Society of Paris has appointed a committee to draw up a proposition to modify the law concerning preliminary imprisonment of medical men in cases of malpractice.

X-rays in Military Surgery.—The Röntgen rays are being employed with great success in cases of gunshot wound among the British troops in India in locating splinters of lead which would otherwise escape detection, as well as fractures and splinters of bone.

Typhus Fever at Skye.—A number of cases of typhus are reported at Skye, a small hamlet near Portree, Scotland. The inhabitants did not know the nature of the disease, and consequently children from infected houses were permitted to go to school. As a result, several members of the teacher's family have been stricken with the disease.

Vaccination or Prison.—A young woman of Atlanta, Ga., was recently fined $25.75 by Recorder Calhoun of that place for refusing to be vaccinated. She was unable to pay the amount and was ordered to serve twenty-five days in the city prison. After having been locked up for three hours she decided to be vaccinated, and was subsequently released after this had been done by her family physician.

The Stringencies of New York Quarantine. — A case of smallpox was discovered on board the Steamship "Edam," which arrived in New York Harbor on December 19th from Amsterdam with 277 steerage passengers. The health officer ordered all on board vaccinated and their detention at Hoffman Island for fourteen days. The vessel was thoroughly fumigated before being permitted to proceed to her dock.

Cattle-fever Quarantine.—The Department of Agriculture has issued a circular to railroads and transportation companies notifying them in regard to a contagious and infectious disease known as splenic or Southern fever which exists in certain parts of the country, and forbidding them to transport any cattle from below a certain line to any portion of the United States, except by rail or boat for immediate slaughter, from January 15th to November 15th of each year.

The Blood of the Buzzard as a Source of Antitoxin.—Dr. Eugene Street of Fall Creek, North Carolina, writes to ask if the blood of the buzzard has ever been tested for antitoxic properties. He suggests that the buzzard seems immune to disease ptomains and toxins, and that it may be within the range of possibility that a principle of more or less antitoxic powers could be obtained from it. Here is an original field of investigation for the ambitious serum-therapeutist.

Another Bogus Dentist Fined.—In New York General Sessions a man was recently fined $500 for practising dentistry under an assumed name, that of a man who was a graduate of a Western dental college and is now dead. The officers of the New York State Dental Society are reported as declaring that in many instances men are practising dentistry under the names of dead persons who held regular diplomas, and, moreover, that there is a regular traffic in dentists' diplomas.

Approval and Disapproval in Georgia of the Marine Hospital Service.—A joint resolution was recently adopted in the Georgia Legislature providing that all quarantine matters be entrusted to the United States Marine Hospital Service, and memorializing Congress to embody this resolution in a National Quarantine Law. The Governor of the State signified his disapproval of it by refusing to append his signature, on the plea that such action was contrary to the doctrine of State rights. Comment is unnecessary.

Explosive Hair-combs.—The explosion of a quantity of celluloid hair-combs which recently occurred on an elevated-railroad train in New York City, draws attention to the dangerously inflammable nature of this substance. In referring to this subject, the *British Medical Journal* mentions the case of a young girl who, while wearing one of these celluloid combs, bent over a lighted candle, with the result that, although the comb had not touched the flame, it exploded from the heat, and the girl was badly burned about the face and eyes.

Smallpox in a Dog.—In the smallpox hospital at Atlanta, Ga., there is a small hairless Mexican terrier which is suffering from the disease. Two weeks ago the dog's master was attacked with smallpox, and was removed from his home to the hospital by the Health Department. Three days later the little dog, which had been in the habit of sleeping with his owner, developed the typical smallpox eruption, and the matter was reported to the health authorities. The dog is now at the hospital with his master, and is being well cared for.

Obituary.—The death is announced of Dr. Joseph Lewi of Albany, N. Y., on December 19th. Dr. Lewi was born in Radnitz, Austria, August 17, 1820. He received his medical education at the University of Vienna, and came to this country soon after his graduation. He was at one time President of the Albany County Medical Society, and at the time of his death was the senior member of the Board of Censors of the New York State Medical Society. For twelve years he served as a member of the State Board of Public Instruction, and refused re-election after four terms of service.

Dangerous Lay-Press Prescriptions.—The *British Medical Journal* comments upon the appearance of a dangerous prescription which recently appeared in the "Answers to Correspondents" column of an English paper called *The Hearth and Home*. The prescription is as follows: "℞ Potass. bromidi, grains 10; Liq. strych., *m.* 5; Tinct. cinch. co., ʒ ½; aq., ʒ ss. Misce. Ft. haustus, 6 ter die." The fact is pointed out that strychnin and bromid of potassium are pharmacologically antagonistic and chemically incompatible, and also that in the above

mixture they form a combination of a most dangerous character.

The Antivivisection Bill Again in Congress.—Senator Gallinger is reported in the *Congressional Record* of December 15, 1897, as saying: "Upon solicitation from several senators saying that they were receiving letters from constituents protesting against the passage of the bill, I allowed it to drift along. On the 13th day of May the bill was again reported and is on the calendar. At an early day I shall move to take up that bill, which is *Senate Bill 1063, Calendar No. 136.* I trust that when I ask the consideration of the bill it may not be objected to, but that that matter which to my mind is extremely important—and a controverted matter, I will say, on the part of physicians, scientists, and humanitarians—may have a fair discussion, and that we may have a vote of the Senate deciding whether or not that bill shall pass this body."

Requirements of the Various States Regarding the License to Practise Medicine.—To obtain a license to practise medicine it is necessary to pass an examination in the following States: Alabama, Delaware, District of Columbia, Florida, Georgia, Idaho, Louisiana, Maine, Maryland, Massachusetts, Minnesota, Mississippi, Montana, New Hampshire, New Jersey, New York, North Carolina, North Dakota, Oregon, Pennsylvania, South Carolina, Utah, Virginia, Washington, and West Virginia. Examination is required although certain diplomas are recognized as an equivalent in the following States: Arkansas, Colorado, Connecticut, Illinois, Indiana, Iowa, Missouri, Oklahoma, Rhode Island, Tennessee, Vermont, Wisconsin, New Mexico. A diploma only is required in the following States: California, Kentucky, Nebraska, Ohio, South Dakota, Texas (practically). The law practically imposes no restriction in the following: Alaska, Arizona, Kansas, Michigan, Nevada, Wyoming. Dr. D. C. Newman of Seattle, Wash., writes us that the law requiring a license to practise medicine in that State is practically a dead letter, for it is never enforced, and adds that fully one-fourth of the practising physicians of that State have never complied with it.

Hospital and Dispensary Abuse in Boston.—The Boston Medical Society, at its meeting December 18th, 1897, adopted the following resolutions: "*Whereas*, the unrestricted abuses of medical charity in the great hospitals and dispensaries of Boston is being seriously complained of by a large number of general practitioners; and *whereas*, the State has granted charters to these hospitals and dispensaries for the definite purpose of giving medical and surgical care and treatment to indigent persons within the city and commonwealth; and *whereas*, the Boston Medical Society, individually and collectively, recognize, with every feeling of sympathy, the rights and just claims of some of our citizens to the benefits of public and private charity, and will not be found wanting in generosity in whatever may tend to foster the moral, social, and physical well-being of the sick, the poor, the destitute, the lowly, the worthy, and the unfortunate; and *whereas*, large numbers of persons, of both sexes, frequently, daily, and repeatedly receive medical and surgical advice and treatment gratuitously for numerous cases of minor surgery and ordinary illness who are believed to be financially competent to pay moderate fees; and *whereas*, the time, facilities, and attention at the dispensaries being necessarily limited, that which is received by the well-to-do and the undeserving is, in that proportion, withheld from those who, by the chartered rules of these institutions, are justly entitled to their benefits; and *whereas*, the practitioners of medicine and surgery of any community, who have duly graduated from accredited medical colleges, and have incurred the expense of locating in such communities, naturally and justly feel that their present and prospective rights and privileges are wrongly encroached upon by the abuses now in practice in connection with medical charities. Therefore, *resolved*, that it is the opinion of this society that some means can be found to check or modify this formidable evil; and, *resolved*, that an urgent call be made upon all such members of the profession who are in sympathy with the movement, and have at heart the best interests of the medical profession, to render such moral assistance and financial support in the adoption of such measures as will tend to eradicate and prevent these evils, abuses, and practices; and *resolved*, that an open meeting be held in the near future, and the profession at large be invited to be present; and *resolved*, that a copy of these resolutions be sent to the *Boston Medical and Surgical Journal, Journal of the American Medical Association, Medical Record, New York Medical Journal*, and THE MEDICAL NEWS for publication. Signed for the Society, M. GERSTEIN, M.D., Secretary, 1038 Washington street."

SPECIAL ARTICLE.

FINAL REPORT TO THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK OF ITS COMMITTEE ON THE ABUSES OF MEDICAL CHARITY.

(Transmitted December 27, 1897.)

MR. PRESIDENT AND GENTLEMEN: Report has already been made of the work done by your Committee on the Abuses of Medical Charity since its appointment one year ago. In its final report, here presented, the committee offers for your consideration and approval the text of a Dispensary Bill which it is proposed to have introduced in the Legislature during the early days of the approaching session. This bill, which has been prepared by the Joint-Committee on Medical Charity Abuse, has received the endorsement of the several committees appointed, with power, by the New York State Medical Association, New York County Medical Association, New York Medical League, New York Society for Advancing the Practice of Medicine, Kings County Medical Society, Kings County Medical Association, Brooklyn Medical Society, Brooklyn Medical Association, and the Long Island Medical Society.

The text of the bill is as follows:

SECTION 1. By and for the purpose of this act, a dis-

pensary is declared to be any person, corporation, institution, society, association, or agent, whose purpose it is, either independently or in connection with any other purpose, to furnish, at any place or places, to persons non-resident therein, either gratuitously or for a compensation determined without reference to the value of the thing furnished, medical, or surgical advice, or treatment, medicine or apparatus; provided, however, that the moneys used by and for the purposes of said dispensary shall be derived wholly or in part from trust funds, public moneys, or sources other than the individuals constituting said dispensary, and the persons actually engaged in the distribution of the charities of said dispensary.

SEC. 2. Six months after the passage of this act it shall not be lawful for any dispensary to enter upon the execution, or continue the prosecution of its purpose unless duly licensed by the State Board of Charities as hereinafter provided.

SEC. 3. Upon the filing with the State Board of Charities of an application and statements in such form and of such substance as shall be prescribed by said Board, said Board may issue a license in such form as it shall prescribe to any dispensary, if in the judgment of said Board the statements filed and the evidence submitted therewith indicate that the operations of said dispensary will be for the public good.

SEC. 4. The State Board of Charities is hereby empowered to make rules and regulations, and to alter or amend the same, in accordance with which all dispensaries shall furnish, and applicants obtain, medical or surgical relief, advice or treatment, medicine or apparatus, but nothing in this act contained shall be construed to mean that said Board shall have power to determine the particular school of medicine in accordance with which any dispensary shall manage or conduct its work, or to determine the kind of medical or surgical treatment provided by any dispensary.

SEC. 5. When it shall appear to the satisfaction of the State Board of Charities that any dispensary licensed by it under the provisions of this act has violated any of the provisions of this act, or any of the rules and regulations made by the said Board under authority of this act, then, and in that event, the said Board is hereby empowered, due notice and an opportunity for a hearing having been given to said dispensary, to suspend or revoke the license of said dispensary.

SEC. 6. Six months after the passage of this act no dispensary shall make use of any place commonly known as a drug-store, or any place or building defined by law or by an ordinance of a Board of Health as a tenement-house.

SEC. 7. Six months after the passage of this act it shall not be lawful to display or cause to be displayed in any manner whatsoever anything which could directly, or by suggestion, make public the existence of the equivalent, in purpose and effect, of a dispensary.

SEC. 8. Any person who violates any of the provisions of this act, or any of the rules and regulations made and published under the authority of this act, shall be guilty of a misdemeanor, and, on conviction thereof, shall be punished by a fine of not less than ten dollars, and not more than $250.

SEC. 9. Nothing in this act contained shall in any wise be construed to abridge any of the powers of the said State Board of Charities, or of any of the members or officers thereof, or inspectors duly appointed by it, now existing under and by virtue of Chapter 546 of the Laws of 1896, known as the State Charities Law.

SEC. 10. This act shall take effect immediately.

As will be seen, this bill differs essentially from that with which the first report of your committee had to deal, the most important feature being that each and every dispensary must obtain a license from the State Board of Charities, by virtue of which its operations shall be conducted; and that, in case the law, or the rules and regulations framed by the Board be not complied with, said Board is empowered to revoke the license of the dispensary so offending. The vested rights of corporations will in no wise be interfered with, and the effort to correct the crying abuses now so widely prevalent will not result in injury to those institutions which are, and will be, properly and conscientiously conducted. This bill, as now presented, embodies the result of much paintaking and earnest consideration, and it is hoped that it will receive the hearty and unqualified support of those who have the subject of the correction of medical charity abuse nearest at heart. The State Commissioners of Charity have already been informally consulted regarding its provisions, and a copy is about to be sent, together with other literature, which has been prepared, to every legally constituted medical society in the State for indorsement.

It is not the idea of your committee that the universal abuse of dispensary privileges can either be done away with or even adequately controlled all at once, but the enactment of a law, such as provided for in the accompanying bill, will, in its opinion, mark an era in the effort which, during the past twenty years, has been made by so many earnest workers toward this end. Experience has shown that without a law on the statute books, just and equitable alike to the laity and the members of the medical profession, absolutely nothing can be accomplished in the direction of bettering existing conditions, and, therefore, it is with the full confidence that the Medical Society of the County of New York will heartily indorse the action of its committee, and will attach its seal of approval to this amended Joint-Committee Dispensary Bill that this report is submitted.

For the Relief of Migraine.—Excellent results are reported by ESHNER from the administration in this affection of the fluid extracts of gelsemium and cannabis Indica. The dose is 3 to 5 drops of each, given three times daily, until physiologic action becomes apparent.

CORRESPONDENCE.

AN ANSWER TO DR. MUNDE.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: I have noticed in the issue of your journal of November 27th a letter from Dr. Paul F. Mundé in which he offers several criticisms of my article on "The Treatment of Abortion," which appeared in THE MEDICAL NEWS of November 6th,

With reference to Dr. Mundé's criticism of the name applied to the large, blunt curette, I beg to say that I have seen the one I use offered for sale in one shop as Mundé's, and in another as Lusk's. So far as I know, it was Dr. T. G. Thomas who introduced the dull, wire curette for scraping the inside of the uterus, and in my opinion an instrument does not become a new one by being made larger and stronger, and used for a kindred purpose. I take, therefore, all intra-uterine dull wire curettes to be essentially Thomas' dull curettes as opposed to Sims' sharp curette, and, if Dr. Mundé is the first who described their use in obstetrics, which I can neither affirm nor deny, his merit in this regard consists in extending the principle of Thomas' curette from gynecologic to obstetric surgery.

As to the other three criticisms, they only prove that Dr. Mundé, on the points in question, does not agree with me, in which he has the same right as anybody else.

H. J. GARRIGUES, M.D.

NEW YORK, December 14, 1897.

CONSTANTINOPLE LETTER.[1]

FROM GEO. R. FOWLER, M.D.,
OF BROOKLYN, N. Y.

MASSING THE TURKISH TROOPS AT THE "SELAMLIK"—THE YILDIZ HOSPITAL—DJEMIL PASHA—TRANSPORTATION EQUIPMENT—THE GERMAN RED CROSS SOCIETY'S WORK—ASEPSIS IN TURKEY—CONSERVATISM OF THE TURKISH SURGEON—THE GRAS RIFLE—THE HAIDA PASHA HOSPITAL—FLORENCE NIGHTINGALE—TURKISH CEMETERIES—EDUCATION OF MILITARY MEDICAL OFFICERS—MILITARY CADETS—THE HOSPITAL CORPS—THE RED CRESENT—THE X-RAYS IN TURKEY.

CONSTANTINOPLE, August 4, 1897.

IN response to a request through our efficient *chargé d affaires* here, Mr. Riddle, Muchir Theoket Pasha, the commander of the Second Turkish Brigade, in whose district the *Yildiz Hospital*, the largest military hospital in Constantinople, is situated, detailed an adjutant to conduct me to the latter institution. While waiting for the horses to be saddled the Pasha invited me, with true Turkish hospitality, into the beautiful garden adjoining his headquarters, from which point an extensive view of the Bosphorus, with Scutari in the distance, is obtained. There I partook of a refreshing ice and a delightful cup of coffee. By the aid of German, of which the Pasha possessed some knowledge, and the Turkish and English of our dragoman, I endeavored to obtain some information as to the number of Turkish troops, as well as the losses sustained during the recent Greco-Turkish war. With characteristic Turkish caution, however, the Pasha was not disposed to talk very freely upon this subject, but from other sources it was learned that, of the 750,000 men which constitute the war footing of Turkey, less than one-fifth were sent to the front. Certainly there are not less than 10,000 soldiers in Constantinople at the present time, as I had opportunity of estimating upon witnessing the ceremony known as the *Selamlik*, or visit of the Sultan to the mosque, which takes place every Friday afternoon. At this ceremony the troops in Constantinople and vicinity are massed about the palace and mosque, which are only about 500 yards apart, the opportunity being thus afforded for the Sultan to come face to face with his troops upon this, the only occasion upon which the descendant of the Prophet and Ruler of the Nation leaves the palace grounds.

Arriving at the hospital I was greeted most courteously by the Turkish medical officers. These, for the most part, have had the advantage of a training in France or Germany, and I had no difficulty in obtaining information as to the hospital buildings and their capacity.

The *Yildiz Hospital* is beautifully located upon an eminence overlooking the city, and is not far from the Sultan's palace of the same name. It consists of twenty-two pavilions, built of wood, and lined with heavy sheathing-paper. These pavilions or barracks are placed in regular order upon an extensive plateau, with wide streets between, and were erected in less than a month to meet the emergency caused by the war.

We were shortly joined by Djemil Pasha, who, although but twenty-seven years of age, is the surgeon-in-chief of this large hospital. It is currently reported that this young man owes his exalted position to the fact that he is the son-in-law of a prominent and influential individual at the Sublime Porte.[1]

We learned that the hospital has ample accommodations for 1000 patients. At the present time it contains between 800 and 900. We were informed that in the neighborhood of 3000 soldiers have been treated here for injuries alone since the commencement of the war. With the natural desire to lessen the importance of their losses this may be taken as a low estimate, as this is the hospital in which was received the majority of those who survived the somewhat crude means of transportation frequently employed (donkeys and rough carts). The equipment for transportation purposes at the disposition of the Medical Corps consists of eight ambulances and two hundred litters for the entire Turkish army. Many of the wounded were strapped upon the backs of donkeys and mules, and conveyed in this manner miles to the nearest railroad.

A tour of the grounds, including a well-shaded garden for advanced convalescents, was first made, escorted by

[1] This letter was lost in transit, and only recently came to light. It is considered of sufficient importance and interest to warrant its publication even at this date.—ED.

[1] From what I saw of his work in Constantinople, as well as the impression which he produced at Moscow, where he appeared as the representative of the Turkish Army Medical Department at the International Congress, I am convinced that whatever influences were at work to secure his rapid promotion he is largely deserving of the confidence that is reposed in him.

the Surgeon-in-Chief and his staff, after which the pavilions were inspected in detail, and many interesting cases shown.

Two of the pavilions, until a few days ago, were under the care of Dr. Nasse, assistant to Bergmann, and a corps of surgeons and nurses of the German branch of the Red Cross Society. Upon the eve of their departure to return to their own country, they were entertained at dinner in the Yildiz Palace, at the close of which they received at the hands of the Sultan the gold medal and green military decoration, conferred upon those who have distinguished themselves in the performance of some especially valuable service to the Turkish Government. In the hospital mentioned there are two operating-rooms, provided in a special operating pavilion, one at each end of the building. One of these is used for aseptic cases, while the other is for septic cases. To the fact that the majority of the Turkish military surgeons receive an additional training in France or Germany is to be attributed the care exercised in respect to wound treatment. While this was not always ideal, yet such as it was it excited my surprise. There seemed to be an earnest desire, and in some instances an enthusiastic and well-directed effort, to comply with the requirements of modern aseptic work.

While the Turkish surgeons are strikingly conservative, sometimes to a fault, and energetic and ambitious operative attacks are not encouraged, yet this conservatism is not the result of timidity on the part of the operators. Djemil Pasha has twice sutured the axillary artery, after Murphy's suggestion, for injury of that vessel occurring in the course of the removal of secondary carcinomatous glandular masses in the armpit—a procedure requiring surgical courage and skill decidedly above the average. Almost all of the operations performed at the *Yildiz Hospital* were done by the native Turkish surgeons, a fact to which they called attention with pride.

Here, as at Athens, I was shown a large number of gunshot wounds of joints, particularly of the shoulder and elbow. Singular to say, these occurred, in the vast majority of cases, upon the right side. In many of the instances of joint injury secondary resection had been done, some of which were typical. Cases of amputation were conspicuous by their absence. The Turk is violently opposed to noticeable mutilation, and to this is to be attributed his abhorrence of losing a member. Of the twenty-two cases of traumatic destruction of the eye, enucleation had been positively refused in the larger number. Up to the present time none of these have developed sympathetic ophthalmia. In those in which the globe was removed in connection with operations upon the orbit, the authorities had at once supplied an artificial eye, of which the wearer was childishly proud.

The Turkish wounded were rather more severely injured, as a rule, than the Greeks. This is probably due to the fact that the latter were armed with the Gras rifle, which carries a large lead projectile. These were obtained from a supply representing the discarded weapons of the French army, and, in many instances, the pieces were shortened by sawing off the barrel after being purchased by the Greek Government. When employed at short range, however, they are capable of considerable execution. That so many Turks were wounded at short range, and in the head and the upper portion of the trunk, rather serves to contradict the stories of want of coolness, if not actual cowardice, of the Greek soldier, which are current. In justice to the Turk it should also be stated that in no instance was a case observed in which the wound was received from behind. This was likewise true of the Greeks.

A visit was made to the *Haida Pasha Hospital*, in Scutari, upon the Asiatic side of the Bosphorus. This is the hospital made famous as the scene of the labors of Florence Nightingale during the Crimean War. The Turkish authorities in charge seemed to evince some interest when reference was made to the work of this noble and self-sacrificing woman; although her labors were of inestimable value, not even a tablet commemorates her services. This is not to be wondered at, however, when one considers some of the peculiarities of the Turkish character. The average Turk lives only in the present. He puts the past behind him as soon and as far as he may, and devotes but very little thought to the future. Only a short walk from the spot where Florence Nightingale won the love and admiration of the civilized world is to be found the largest Turkish cemetery about Constantinople, where lie the remains of many of the highest dignitaries, as well as warriors and statesmen, that Turkey has ever produced; for the soil of Scutari is considered sacred ground. Here the Ottoman dynasty was founded, and from here Islamism spread itself in Europe. Many illustrious men, therefore, have been buried here. The condition of the place would disgrace the potter's field of the meanest hamlet in Christendom. The tombstones, many of which are painted green to indicate the grave of a descendant of Mahomet, are to be seen leaning in all directions in a shiftless, tumbled-down manner, and many have fallen and are half buried beneath the *débris* of broken-down branches of the Oriental cyprus, the invariable accompaniment of a Turkish burial-place. There is no railing about the place, and the dogs, idlers, and cattle rove about its three-mile area at will. That this was not due to the fact that it is no longer used as a cemetery was attested by the presence of a newly made grave, the freshly painted green tombstone of which, surrounded by a carved turban in many folds, proclaimed the importance during life of its occupant.

I could not help contrasting this with the well-kept English cemetery within sight of the spot where I stood, in which lie buried many of the English officers who died here during the Crimean War.

The *Haida Pasha Hospital* is now only occupied by convalescents, these being principally medical cases. Typhoid fever formerly prevailed here to a considerable extent; but, since the water-supply has been changed and water has been brought in casks from the mountains, it has been greatly lessened.

I was somewhat surprised to find that both Armenians and Greeks are serving at the present time in the Turkish Army Medical Corps. It is a fact that only the faithful followers of the Prophet are allowed to fight under

his banner, and to join its actual combatant rank and file.

The Turkish military medical officer has a special training, and this at the expense of the government. Upon passing his examination and receiving his commission he pledges himself to serve the government twenty-six years, at the end of which time he may be pensioned. If for any reason other than actual physical disability this obligation is not fulfilled, he is forced to refund to the government the amount expended by the latter upon his education.

About one-fourth of the classes at the University of Constantinople are entered as medical students, or about 500 yearly. While at first glance this seems like a large class, yet it should be remembered in this connection that this is the only school in which medicine is taught in Turkey. There is a special department of military medicine, which, together with the regular course, covers six years. In the case of those intending to practice in civil life the examinations are conducted by a civil board, but those designed for the army or navy must pass an examination at the hands of a board of military surgeons.

A surgeon and an assistant surgeon are assigned to each battalion. In addition to these, *medical cadets*, who have attended two or more courses of lectures and demonstrations, are placed under the orders of the medical officers. These are selected from among those who have but a limited preliminary education, and who are not deemed of sufficiently promising material to do credit to the service in the higher grades. The medical cadet may, however, aspire to the latter, and occasionally succeeds in obtaining a commission. Usually, however, he spends his life in performing the most menial duties of the medical service, these including cupping, bleeding, tooth-drawing, and such services as were demanded of the old-time barber-surgeon of the European armies.

The hospital corps consists of non-combatants enlisted for the purpose. Upon occasions of ceremony they parade as a separate organization. This corps corresponds in some respects to the ambulance corps of our National Guard. It is much below the latter in efficiency; for the reason that its members are not trained in rendering first aid to the injured. The brassard is a *red crescent*. The natural aversion of the Turk to anything in the shape of a cross forbids the adoption of the insignia of the Geneva convention. The corps flag is a green field with a red crescent. The corps numbers 3000 for the entire army, including hospital stewards, who must be regular graduates in pharmacy, and pass a special examination before admission. The hospital corps is especially trained in the transportation of the wounded and care of the sick, but its members are not expected to render first aid, save of the simplest character.

The discovery of Röntgen has found its way into Turkey and has been utilized by the medical department of its army. Several cases were shown in which missiles have been located by the aid of the X-rays, and their removal successfully accomplished. The erratic course of the missiles and their inaccessibility rendered their localization impossible by any other means.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

PATHOLOGICAL SOCIETY OF PHILADELPHIA—PHILADELPHIA COUNTY MEDICAL SOCIETY—SOME COMMENTS APROPOS OF THE RECENT OUTBREAK OF DIPHTHERIA AND ENTERIC FEVER.

PHILADELPHIA, December 25, 1897.

AT the last stated meeting of the Pathological Society of Philadelphia, held on December 23d, Dr. Joseph Sailer read a paper on "Results of Laceration of the Brain Substance," based upon the following experiment: A cat having been anesthetized, a trephine opening was made in the skull large enough to expose a rather large area of brain substance, into which a hot platinum needle was then plunged, and moved to and fro in order to lacerate the organ; the wound was then dressed aseptically, and the animal placed under observation. At the end of seventy-two hours the animal died, the brain was removed, and sections were cut from areas near and remote to the site of the lesion and stained by appropriate methods. Microscopic examination of these sections showed that in the vicinity of the clot which resulted from the hot needle, the neuroglia cells had proliferated and were noticeably increased in size, and that extensive degenerated changes in the neighboring ganglion cells had ensued; karyokinetic figures were not observed. Away from the immediate site of the lesion no abnormalities were apparent. Dr. W. E. Hughes reported two interesting cases of Weil's disease occurring in men of middle age. The first case, after a vague history of malarial infection some months before, suddenly developed acute jaundice, hematuria, irregular chills, and hyperpyrexia, followed by rapid collapse and death; *post-mortem* findings showed an enlarged spleen, kidneys, and Pyer's patches, with advanced fatty degeneration of both suprarenal capsules. In the second case, sepsis resulting from an urethral stricture for which perineal urethrotomy was performed, preceded anuria, jaundice, signs of acute hepatic and renal congestion, and obstruction to the venous return flow. In both cases extensive small round-cell infiltration of the capsule of Glisson, and acute parenchymatous degeneration of the liver were found after death. Dr. Joseph McFarland and Dr. J. M. Anders reported a case of pneumothorax in which the site of the perforation had been discovered, this joint-paper including a careful *résumé* of the literature of the lesion, and its discussion from a pathologic standpoint.

At the last stated meeting of the Philadelphia County Medical Society, held on December 22d, Dr. Joseph Price read a paper on "Operative Detail in Appendicitis," in which he advocated a radical operation in cases demanding operative interference at all, and in which many minor details of the procedure were elaborated; he described, among these, a method by which sutures are introduced before final severence of the appendix, thus obviating to a large extent, the speaker claimed, the risk of infection through the wound. Dr. Williams F. Arnold gave a most interesting account of "Some Personal Observations on the Bubonic Plague," which he made in Hong Kong and its environs in 1894. Speaking of the specific cause of this disease, Dr. Arnold said that he had been unable

to convince himself of the specificity of Kitasato's plague bacillus, and that he thought rather that Yersin's bacillus was the true cause of the disease. He seemed to be favorably impressed with the results of Yersin's serum-treatment of the plague, by the use of which he had seen the mortality fall from 80 or 90 to 50 per cent. in severe cases, and from 50 to 10 per cent. in mild cases. Dr. Milton B. Hartzell reported an unusual instance of epithelioma occurring in a boy of fourteen years; the growth was situated at the left ala of the nose, with slight secondary involvement of a small area around the outer canthus of the left eye. It was removed by the local use of pyrogallic acid, healthy cicatrization following this treatment. Dr. Edward Jackson reported a case of ivory exostosis about the size of an almond, growing from the lateral aspect of the nasal side of the orbit, the removal of which he accomplished without difficulty. The speaker also referred to two other cases of a like character, and showed a specimen of the growth. Dr. J. B. Learned read a paper on "The Induction of Sleep by Means of Producing Muscular Fatigue in the Patient," an original feature of which was his advocacy of slow breathing, instead of rapid respiratory movements, as usually recommended for hypnotic effects.

The resources of the Philadelphia health authorities have been greatly taxed during the recent outbreaks of diphtheria and typhoid fever—taxed, it would appear, to an extent which left them completely distanced in the race between health and disease, for the infection spread merrily on, involving whom it chose in what would have been called an epidemic, had the nature of the infection been, for instance, some imported tropical fever, or smallpox. But being only diphtheria and typhoid, to which tuberculosis is, of course, a necessary adjunct to every respectable community—particularly communities with Health Boards—the outbreak had to sink its identity in the official obscurity of "a prevalence in certain sections" of the diseases in question. The epidemic, for such it certainly was, has now subsided, some say because of the intervention of the Board of Health; others, less charitably inclined, say it was because it ran its course. At all events, it has subsided, but at the cost of many lives, and leaving in its wake an unsavory odor of general public mistrust in our methods of municipal hygiene. And is the public, after all, so far wrong in its judgment? What, with foul water, inadequate food-inspection, and a whole host of relics of municipal insanitation of a past era still flourishing here, is the public to infer? Is it not natural for it to place greater confidence in personal immunity and prophylaxis rather than upon the labors in its behalf made by its health and legislative bodies? The time has come for this city to possess a modern water-supply, to abolish with a firm hand nuisances which would not be tolerated for a moment in many centers, to equip its medical-inspection officers with every facility for the intelligent pursuance of their work, and, finally, to legislate so that for such necessities as these she will not be dependent upon the humor of a clique of politicians whose ideas of sanitation and public health are distinctly subservient to the machinations of practical politics, and to the pecuniary plums with which other forms of legislation fill their councilmanic pockets. Councils must be importuned for every improvement needed by the Board of Health, and with the approval of this body only may the present inadequate equipment for coping with epidemics be made effective. The question, therefore, can be solved only by the entire cooperation of both bodies, or by the complete divorce of the one's dependence upon the other. The former seems futile of accomplishment; the latter is palpably impossible. And thus the situation remains, to the detriment of the health of the city at large, and as a tremendous handicap to the efforts of the Board of Health in dealing with these outbreaks of endemic infections, such as the two which have just terminated.

OUR BERLIN LETTER.

[From our Special Correspondent.]

A NEW OPINION ON THE THYROID QUESTION—THE IMPORTANCE OF MIXED INFECTION IN TUBERCULOSIS—AMYLOID DISEASE DUE TO STAPHYLOCOCCIC, BUT NOT OTHER BACTERIAL PRODUCTS—LONG INCUBATION OF GONORRHEA AND ITS SIGNIFICANCE—PROFESSOR MOMMSEN'S EIGHTIETH BIRTHDAY.

BERLIN, December 18, 1897.

PROFESSOR HERMANN MUNK'S article on the "Thyroid Gland" which appeared in the last number of *Virchow's Archives* has naturally attracted a great deal of attention. The Professor of Physiology at the University of Berlin and the successor to the chair of Du Bois Reymond would be deferentially listened to in any case, but besides, Professor Munk's own work in physiology has given him a place among the greatest living workers in this line. It is a little startling to find that he does not agree with the generally accepted theories as to the thyroid gland in animals being essential to life, or that its function is necessary for the proper performance of the processes of nutrition. For years he has been known to hold such opinions, but his reassertion of them now, after a long series of careful experiments in the face of the supposed acquisitions to physiology and therapeutics which prevailing opinions involve, has appeared somewhat in the light of a medical sensation. He states very definitely what are considered to be the cardinal points of the present physiology of the thyroid gland: (1) That animals cannot exist without it. (2) That where death is not immediate a cachexia develops resembling myxedema in the human species, or the so-called cachexia strumipriva after surgical removal of the gland. (3) That the implantation of the thyroid or its internal administration will obviate the symptoms caused by its removal. He then categorically denies each one of these principles and also the doctrine as a whole.

As to animals dying sooner or later as a consequence of the removal of the gland, while in his experiments of ten years ago all animals perished after the operation, now fifty per cent. of the apes and rabbits, and twenty-five per cent. of the dogs and cats are not affected at all by removal of the thyroid. The difference in the results of the operations performed with the antisepsis of 1887 and the asepsis of 1896 and 1897 is a very suggest-

ive series of experiments for the modern surgeon to study. The completeness of the experiments seems to eliminate any chance of error. That the thyroid was thoroughly removed was made positive from the results of autopsies in a number of cases where the animals were killed after months and sections made to decide this point. Nor did any organ develop to replace the supposedly necessary function of the gland. The parathyroids played no such rôle, as they were always carefully sought and removed, except in one instance in which they were left and the animal subsequently died, but the *post-mortem* did not reveal any tendency to compensatory hypertrophy. The hypophysis was very carefully examined in a number of cases to be sure that it did not develop a compensatory function, but no evidence of any change was ever found, and no thymus nodules took on regressive activity to replace the romoved thyroid.

As to the myxedematous cachexia so often described, he has never observed it. He has frequently seen animals die some months after the operation from a progressive wasting, seemingly without cause, but the changes present could never be described as myxedematous. The lesions usually (*post-mortem*) found were those of a chronic gastro-intestinal affection. This was probably due to the well-known tendency of animals to die during captivity from nutritional disturbances because of the unsuitable food and insufficient exercise. By no means all the experimental animals died, but on the contrary, many of them grew fat after the operation. Professor Munk especially criticizes Horsley's two series of experiments on apes. The first is the basis of all the claims which have been made for the development of myxedema in apes. In it, all the apes that did not succumb to the operation became myxedematous within from four to seven weeks. During the last year or two Professor Munk has had thirteen out of seventeen apes live from one to nine months after the complete removal of the thyroid gland, but has observed the development of nothing like myxedema. Some of the comments on Horsely's work and his failure to answer Professor Munk's request to be shown a myxedematous ape or a photograph of one are rather caustic.

As to the question of implanted or ingested thyroids preventing the accidents remote or proximate which follow thyroidectomy, Munk has never observed any such effect. It certainly does not prevent the immediate accidents. The cachexia which so often develops after the operation as the result of captivity, etc., is not influenced by thyroid medication, Professor Munk quotes, in this regard, the work of a number of others who have reached similar conclusions; for instance, one set of observations are detailed in which a fair percentage of thyroidectomized animals survived without thyroid feeding or implantation, while eleven out of twelve, the thyroids of which had been extirpated, and to which thyroid extract had been given as food, died within a few weeks.

Tetany has sometimes been observed after the removal of the thyroid, but it is very irregular in its manifestations, sometimes occurring immediately, sometimes not for some time, and is often interrupted by irregular intervals, during which no spasms occur. All these irregular phenomena point to other conditions for their origin besides the extirpation of the thyroid, which, of course, was a constant factor in the observations. The course of the tetany does not seem to be modified by thyroid medication.

The important question in the study of tuberculosis throughout the German medical world just now, apart from the erection of institutions for its treatment, is the influence of mixed infection on its course and fatality. Some time ago Dr. Michaelis, working in Professor Leyden's clinic, was able to demonstrate staphylococci in the blood of eight out of ten tuberculous patients. Some recent work from Professor Stadelman's clinic more or less confirms the studies of Michaelis, though the percentage of cases in which the staphylococci could be demonstrated was not so high.

A special feature of the work in Professor Stadelman's clinic was the determination by inoculation experiments that the staphylococci found were not especially virulent, but, on the contrary, seemed to have lost their virulency owing to unfavorable circumstances for their growth in the organism. Petruschky, some time ago, observed the same lack of virulency in the streptococci which he had found in the blood of tuberculous patients. The explanation of this would seem to be either Spengler's theory that bacterial growth in the non-succulent cicatricial tissue of tuberculous cavities, in an unfavorable medium, leads to the loss of certain vital properties, or that the comparatively slow growth and the consequent gradual absorption of toxins leads to the formation of certain antitoxic and immunizing agents in the blood which react unfavorably upon the vitality of the streptococcus.

An interesting commentary on the whole subject is the very thorough review of amyloid degeneration which appeared in a recent number of *Virchow's Archives*. Dr. Davidsohn, of Virchow's laboratory, at the suggestion of his chief, has reviewed the literature of this subject, and confirmed by a series of careful personal investigations the results of those observers who claim to have experimentally produced amyloid disease in animals. With the immense material of the Pathological Institute in the Charité to draw from for comparative studies in amyloid disease in man, his conclusions may be accepted as absolutely final.

Dr. Davidsohn has been able to experimentally induce amyloid disease only with injections of staphylococci and their products. Streptococci, though carefully experimented with, did not lead to amyloid degeneration, neither did carefully graduated doses of more virulent bacteria, nor the injection of putrefactive material. The work of others with tubercle bacilli he considers amply sufficient to prove that they alone never produce amyloid degeneration, which somehow seems to be the specific effect of the staphylococcus.

Dr. F. Bruck, in the last number of the *Allgemeine Medicinische Central-Zeitung*, reports a case of gonorrheal infection in which all the circumstances seem to point to an incubation-period of thirty days. The case was carefully studied, and there seems no reason to doubt the facts or the conclusions drawn from them. Such cases

are not so rare as they used to be, and generally are not received with the air of incredulity which was formerly customary. Lesser, here in Berlin, and Finger in Vienna, consider that the possibility of a gonorrheal infection running a very subacute course so that no symptoms are to be noted and yet later lighting up into an acute process cannot be entirely excluded. It is the same principle as that involved in the question of chronic gonorrhea, which may continue years with practically no symptoms. Acute exacerbations, which were once regarded as reinfections, are now considered to be cases of self-infection from an old persistent focus. There are some interesting possibilities in the medico-legal aspects of these cases of gonococcus infection with very long incubation periods, which seem to make the subject worthy of more than passing attention.

TRANSACTIONS OF FOREIGN SOCIETIES

Vienna.

EFFECT OF DIET IN DISEASES OF THE LIVER—EXPANSION OF THE STOMACH WITH AIR—PERONIN AS A SUBSTITUTE FOR MORPHIN—THE IMPORTANCE OF SKIAGRAPHY IN THE DIAGNOSIS OF CALCULI—PHYSIOLOGY OF THE URINARY BLADDER—UNRELIABILITY OF THE HEMOGLOBINOMETER.

AT the session of the Medical Club of November 3d, KOLISCH read a paper upon the *prognosis and treatment of diseases of the liver*, in which he showed as a result of reasoning as well as from experiments upon animals, it is indisputable that in all cases of severe liver disease life may be greatly prolonged by the restriction of the amount of albumin in the food. If too much of this substance is taken at once, NH_3 remains in the blood, and poisons the individual. To facilitate the removal of toxic products, diuretics should be given, calomel being the best of all. Drugs which produce increased metamorphosis of albumens, such as salicylic acid, are distinctly contraindicated. Preparations of bile or its salts are the best cholagogues.

At the session of November 10th, HERZ described a case of *hysteric expansion of the stomach with air*. The patient was a male aged nineteen years, who, after a period of overwork, suffered so greatly from difficulty in breathing and palpitation of the heart, that he was obliged to remain eight weeks in bed. Later the curious symptom developed that with each inspiration the stomach filled with air, emptying again on expiration. The chemic and motor conditions of the organ remained normal and there was no sign of pyloric stenosis.

OSER has observed several such cases, some of which seemed to be due to intestinal disturbances following the abuse of cathartics. In other cases, the swallowing of air apparently resulted from the alternate action of the constricting and dilating nerves of the stomach.

STAMPFL recommended the use of *peronin as a substitute for morphin*, especially in cases of laryngeal and pulmonary disease accompanied by an irritating cough. By the use of this remedy the cough is made less severe and painless, expectoration facilitated, and reflex vomiting ceases. This drug is also valuable in mild neuralgias. Patients do not quickly become accustomed to its use. As peronin frequently produces itching of the skin and increases diaphoresis, it must not be given to phthisical patients with night-sweats, and cannot be used as a laryngeal insufflation. It has no bad effect upon the heart, and does not constipate.

At the session of November 17th, BUXBAUM spoke of the *importance of radiography in the diagnosis of calculi*. Contrary to the opinion which has sometimes been expressed, he found that all varieties of urinary calculi including those composed of uric acid, cystin, or cholesterin, are impermeable to the X-rays. However, he has had so many failures in his attempts to demonstrate biliary and nephritic calculi in the living, that he is still in doubt as to the true value of this method of diagnosis.

At the session of the Imperial Royal Society of Physicians, November 12th, SCHLESINGER narrated two cases which have a bearing upon the *physiology of the urinary bladder*. A woman, aged sixty-one years, suffered some time with symptoms of paralysis of the sphincter and detrusor urinæ muscles and also with complete anesthesia of the perineum, vulva, and mucous membrane of the bladder, followed later by motor and sensory paralysis of the rectum. At autopsy, it was found that a carcinomatous nodule had almost completely destroyed the fourth sacral segment by means of the pressure it exerted. In another patient, a glioma which was found at autopsy to be situated in the third and fourth sacral segment of one side, produced motor disturbances of the bladder without any loss of sensibility. These cases show that the spinal nerves to these organs are bilateral, and, furthermore, that the controlling center for the rectum is not identical with that of the bladder, but it is situated somewhat lower down.

At the session of November 19th, JELLINEK showed by clinical evidence that there is, even in healthy individuals, *no constant relation between the color of the blood and its percentage of iron*. In pathologic conditions this is even more striking than in the normal. Thus, in anemias the color of the blood is changed much more than the percentage of iron is diminished, while in purpura hemorrhagica the reverse is true. This proves the hemoglobinometer to be an unreliable instrument.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK.

Stated Meeting, Held November 27, 1897.

THE President, JOHN WINTERS BRANNAN, M.D., in the Chair.

DR. JOHN H. HUDDLESTON read the paper of the evening, entitled

VACCINE.

The paper consisted of a collection of interesting notes upon the following subjects: (1) Vaccination in Europe; (2) a good vaccine laboratory; (3) tetanus following vaccination; (4) generalized vaccinia, and (5) vaccinal immunity. The author described the various methods of preparation of vaccine virus employed in Europe, and

stated that vaccination with calf-lymph is generally practised on the Continent, while it is rarely used in England, where human virus is preferred. Vaccine laboratories in Germany are under Government control. The percentage of successful vaccination in Berlin is 96.84; in Hamburg, 94.85. The best laboratory, in buildings and equipments, is that of Cologne, which the author described at length. A case of tetanus following vaccination was referred to, also forty-five cases of generalized vaccinia in patients varying in age from three days to sixty-two years. Twelve of these were vaccinated with bovine virus, either direct from the animal or preserved; 18 with humanized virus; 1 with cow-pox, and 1 with horse-pox by accidental inoculation. The source of the virus in the other cases was not stated. Nine out of the 45 cases were not vaccinated in the usual way; 8 were inoculated with virus from the vaccine vesicle of another person, and the ninth ate vaccine crusts given accidentally with the food. Seven of the cases terminated fatally as a result of some complication. In regard to vaccinal immunity, the author said that little or no immunity is given the fetus by vaccination of the mother, as shown by Wolf and Gast, who vaccinated respectively sixteen and seventeen women in various stages of pregnancy and subsequently vaccinated the children with complete success. Natural immunity is so rare that those who have seen the largest number of vaccinations are least inclined to admit the possibility of its existence. Immunity is acquired slowly through the medium of vaccination. Repeated experiments have been made by vaccinating a person daily until the vaccinations failed to take, and it has been found that immunity is usually secured within from seven to ten days. The duration of the immunity when obtained is extremely variable; in some cases it apparently lasts a lifetime. Allbutt has reported the case of a woman who was successfully vaccinated three times, and who had smallpox three times. At North Brother's Island, New York, where patients are vaccinated on arrival, it has happened that persons repeatedly sent there have, on each occasion, been successfully vaccinated, revaccination having followed within six months of the first inoculation. Buchanan has reported a series of cases occurring in prisoners in which successful revaccination followed the first inoculation within a very short time—in 4 cases within less than a month; in 9 within two months or less; in 3 within three months or less, and in 12 within six months or less.

DISCUSSION.

DR. FRANK H. DANIELS: I have at present a child under observation whom I have unsuccessfully vaccinated three times. The mother tells me that she has never been vaccinated with success, although several attempts have been made. I used fresh vaccine, and I am going to try again, but it has occurred to me that this may be a case in which there is an inherited immunity.

THE PRESIDENT: I remember seeing a case some years ago at North Brother's Island in which a man was vaccinated and the pustule formed; in spite of this smallpox was contracted, and the two processes went on at the same time. The patient had a most malignant form of the disease, and died of it while the vaccinia was still going on. It would be interesting to know whether many such cases have been reported.

At a recent meeting of this society I spoke of a fluid vaccine which I employed in vaccinating six adults; it was successful in every case, but in all there was a good deal of trouble while the process continued, several patients developing abscesses in spite of the fact that I took antiseptic precautions before using the vaccine. I am not now so enthusiastic about fluid vaccine as I was at that time, and would like to ask if the unpleasant effects in these cases were due to the preparation employed.

DR. HUDDLESTON: The President's question immediately brings to mind what is known concerning "germ-free" lymph. It is at present impossible to collect vaccine virus without germs. But two different, and partially successful, methods of sterilizing virus have been discovered; one consists of the centrifugalization of virus which has been diluted with water, and the second, of mixing the virus with varying proportions of glycerin. The former method reduces the number of bacteria present, but does not entirely remove them; the latter is much more effective, and by means of it the number of germs in lymph, as tested by making cultures on agar, can always be materially reduced within a period which varies from a few days to a few weeks. Sometimes this does not secure sterility, but when old glycerinated virus is not sterile the inference simply is that the germs present are such as resist the action of glycerin; the bacillus subtilis, for instance, which is non-pathogenic, is unaffected by glycerin. It may then be fairly stated that lymph practically, although not absolutely "germ-free," can be secured with considerable certainty. The results from the use of this so-called "germ-free" lymph, whether absolutely sterile or nearly sterile, have not, however, secured freedom from the inflammatory complications of vaccine. On the contrary, it is the general testimony given by those who have experimented at length with such lymph that inflammatory reactions occur in about the same proportion of cases as before this lymph was introduced, and also that not merely inflammatory complications are present, but occasionally vaccinal eruptions as well. At Hamburg vaccination of 1700 primaries with "germ-free" lymph gave eight cases of skin eruptions. The Imperial Berlin Commission recently reported that in its judgment inflammatory appearances are due, first to the condition of the person vaccinated, second to the greater or less amount of effective lymph in the material applied, and, third, to the technic employed in the inoculation. The commission stated that inflammatory complications are especially frequent if the incisions made in the inoculations are numerous, long, deep, and close together. It is a familar fact that inflammation is more frequent in secondary than in primary vaccination. It is also unfortunately the case that a number of German reports state that quite thorough disinfection of the arm by means of sublimate solution and ether before vaccination does not prevent all inflammatory complications, but in some cases has actually seemed to increase them. Nevertheless, it has

been a great advantage to vaccine production that practically germ-free lymph may be obtained; because the germs present, while, as a rule, non-poisonous, are, it is thought, injurious to the vaccine organism, and it is a fact, that by employing "germ-free" lymph, the so-called "purulence" in the producing animals, one of the former bugbears of the vaccine laboratory, has practically disappeared.

Finally, it should be added that while every brand of vaccine has its own bacterial flora, the few germs which are common to almost all are very clearly non-pathogenic to men or animals. Repeated inoculations of germ-bearing lymph have been made in guinea-pigs, rabbits, and other test animals, and almost invariably without any pathogenic results.

DR. REYNOLD W. WILCOX then read a brief paper, entitled

BOERHAAVE ON THE CANINE MADNESS.

Before reading his paper, Dr. Wilcox said he wished to correct some inaccuracies which appeared in the report of the last meeting as published in a recent number of THE MEDICAL NEWS. In speaking of Pasteur Institutes, he did not refer especially to any one. Nor did he mean to convey the idea that all patients died who received antirabitic treatment at such institutions. What he said was, that those patients who did die after receiving the treatment, died at about the same length of time after the inoculations. Again, in speaking of the symptoms described by Dr. Cabot as occurring in animals inoculated with rabies as similar to those which took place in guinea-pigs which he had inoculated with cod-liver oil for experimental purposes, he referred to the so-called alkaloids of cod-liver oil.

The author first spoke of the variations in the period of incubation of hydrophobia in the human being, as given in the old books, in which it is variously stated as being from twenty-four hours to as long a period as forty years, and repeated his statement made at the last meeting that there is no known infectious disease with such an indefinite incubation period as the one under consideration. He then read extracts from Van Swieten's Commentaries on Boerhaave "On the Canine Madness," published in 1776. He further said that, in carefully looking over the literature of the subject, he had been surprised to find that since 1776 all authors, in writing of hydrophobia, have copied Van Swieten's description of the disease, and that even the most modern writers have copied from each other the self-same description. In a work published as late as 1875 the maximum length of the incubation period is given as three years. To show that inoculation against rabies, with attenuated virus as an immunizing agent, is not an entirely new idea, he read a passage from Van Swieten's book, in which it is recommended that "the burnt liver of a mad dog" be eaten by the person bitten in order to ward off hydrophobia.

DISCUSSION.

DR. WILCOX: I have studied the *post-mortem* findings in persons alleged to have died of hydrophobia, and have learned that it is distinctly stated in the later books that the blood-vessels of the pons and cortex are enlarged and congested, that the perivascular spaces are infiltrated with round cells, and that small hemorrages are also found; whereas, in the old books special mention is made of "dry brain" being present in such cases. I have been trying to recall some of the patients I have seen who were supposed to have suffered from hydrophobia, and I think I have seen twelve, of whom three died. Of those who survived there can be no reasonable doubt but that four were hysterics; one had tic convulsif, and another tetanus; the remainder suffered from fear of hydrophobia. In the three who died the usual *post-mortem* signs of septicemia were found. I repeat that I do not believe there is a definite disease hydrophobia, although I am willing to be convinced of its existence. I do not want to convey the impression that I do not appreciate the work which is being done by Dr. Cabot and others; but as long as no lesion can be demonstrated after death, and not one of the dicta for the determination of an infectious disease, as Koch has set forth, is found, I cannot believe in the existence of hydrophobia.

DR. FOLLEN CABOT: In regard to Wilcox's last remarks I want to say that such criticism is rather stimulating than depressing, for it makes me all the more determined to prove what I believe to be the truth. I am convinced of the existence of a disease which produces certain definite symptoms by inoculations from one animal to another. For instance, the virus which is used in the laboratory of the Board of Health has probably been inoculated into 2000 rabbits here and in Baltimore, and was used many years in Paris. The virus is now a "fixed virus," that is, it produces the same symptoms with death following on about the same day in each consecutive inoculated animal. The rabbit is subdurally inoculated with an emulsion made from the medulla of a rabbit dead from rabies. The animal is apparently perfectly well during six days following the inoculation, then a beginning tremor is noticed, most marked in the hind legs, and combined with weakness; on the seventh day the animal is markedly paralyzed; may be excited, and froth at the mouth; on the eighth day complete paralysis supervenes, and the animal dies any time from the tenth to twelfth day. These animals do not attempt to bite, but open and close the jaws, and have an increased flow of saliva from the mouth. Toward the last the bladder is paralyzed. Guinea-pigs have the furious form of the disease after an incubation period of from five to six days; they then become excited; run around furiously, biting at everything, showing some paralysis of the throat, and an abundant flow of saliva. Paralysis soon begins in the hind legs, and death occurs on about the seventh day.

I have here to-night a guinea-pig and a rabbit which have been inoculated with virus from an animal dead with rabies. The rabbit was inoculated eight days ago and is nearly wholly paralyzed which has been made more marked by transportation and exposure. The guinea-pig is just at the beginning of the stage of excitement of rabies. The animals are not what I intended to show as typical, but I wish any gentleman here, particularly Dr. Wilcox, would come to the laboratory and see many of the ani-

mals in the condition I have described. All cultures made from the emulsion, prepared by mixing a small piece of medulla from a rabid animal and a little water, are sterile to all tests in different media, if not so the animal inoculated will die in different media, if not so the animal inoculated will die of septicemia, always traceable to some impurity which has entered the material during the autopsy or in the process of emulsifying.

DR. SCHRAM reported a case of

CONJUGAL DIABETES.

The patient, a woman, first came under observation seven years ago, at which time she was sixty-nine years of age, and had been married forty-eight years. Sugar was constantly found in the urine in amounts varying from less than one to four per cent. She refused to submit to rigorous diet and died in July, 1897, in diabetic coma. Thirst and pruritus had been the most troublesome symptoms. An extensive ischiorectal abscess developed two weeks before death. One week later the husband's urine was found to contain three per cent. of sugar. Symptoms of the disease sufficient to attract his attention antedated his wife's death by about two weeks. Sugar is now found in his urine in abundance, but disappears for a time under diet and opium. He is now seventy-six years of age and apparently contracted the disease seven years after it was first discovered in the wife and after nearly fifty-three years of married life. The couple had eleven children, seven of whom are alive and well.

In a series of 5000 cases Boisumeau found 1.8 per cent. of conjugal diabetes. Most investigators agree that the development of the disease in both husband and wife is not accidental, but that an etiologic relation exists. The facts thus far published do not shed much light on the two theories of causation now held, *viz.;* (1) that the ordinarily accepted causes of diabetes are active in both husband and wife, and (2) that the disease is contagious. Cases have been reported with almost conclusive evidence of contagion, but the nature of the contagium and how it is conveyed are mysteries.

DISCUSSION.

DR. DANIELS: I should doubt whether it is a question of contagion or infection in such a case as the one reported. The disease could have existed undiscovered a long time. These people had lived together fifty years, and were exposed to identical conditions; therefore, whatever conditions favorable to the prodution of the disease were present in the case of the wife might also have been present in that of the husband. I would rather attribute it to this fact than to contagion or infection, especially as it did not appear in the man until seven years after its onset in the woman.

DR. SCHRAM: In regard to the doubt which has been expressed as to contagion in diabetes, I would like to mention some recently reported cases in which laundresses apparently contracted the disease by washing the clothing of diabetics. However, the question is still an open one. The authorities differ very much, but the French school is inclined to believe that diabetes is contagious.

DR. DANIELS: Some time ago I reported the case of a man, forty years of age, in whose urine sugar was found. He soon contracted syphilis during the early stage of which the sugar disappeared to reappear later on.

Dr. J. P. MCGOWAN: I have a patient, a man thirty-nine years old, who has been under observation four years, and who during years has had more or less sugar in his urine, the amount depending upon his habits, which are not always what they should be. About two years ago he contracted syphilis, and a strict diet and the usual treatment were administered. Sugar entirely disappeared from his urine two months after the occurrence of the secondary symptoms. He was under observation the ten months subsequent to the manifestations of syphilis, during which time frequent examination of the urine failed to reveal any sugar; this fact, I think, was due more to the regulation of his habits than to any special effect of the syphilitic poison.

DR. ROBERT H. GREENE: It is a well-known fact, I think, that sugar often disappears from the urine in diabetics who have been attacked by syphilis, although, so far as I know, no explanation has been given as to why this is so. There are some writers who claim that diabetes proper is always the result of syphilis.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held November 2, 1897.

THE President, DR. C. A. HERTER, in the Chair.

DR. GEORGE W. JACOBY exhibited a patient with a typical case of Thompson's disease. He is a young man who had been referred to him by Dr. Schwinn of West Virginia, with a correct diagnosis. The patient is twenty-eight years of age, and has lived in this country since 1884. There is nothing in the family history especially bearing upon the condition, except that a distant cousin is said to have walked stiffly and in a peculiar manner for fifteen years. The patient himself has always been delicate, but has been as active as other boys. He had typhoid fever in 1889, and on recovering from this first noticed a cramp in the legs. After a little it was found that he could not execute movements as quickly as before. In 1893, he first sought treatment. During the past year or two his arms and hands have also been affected. The condition varies considerably at different times, but is apparently not influenced by meteorologic conditions. The examination showed quick reaction of the eye muscles, with spasm of the external rectus; cramp of the masseter muscles on bringing the jaws together forcibly; no involvement of the pterygoids. All the muscles of the upper extremity and of the thorax are involved—indeed, nearly all the muscles of the body. The contraction of the muscles is decidedly tetanic, and at first was very marked, but, on repeated tests, it gradually subsided. The electric examination showed marked myotonic reaction, and also a wave-like appearance, but Dr. Jacoby could not make up his mind that this latter phenomenon consisted of a series of waves, such as are observed in water. A piece of muscle had been excised from the biceps, and also from the quadriceps, but they had not yet

been minutely examined. The case is quite characteristic on account of the marked variations occurring from time to time. The speaker said that in an article published by him ten or more years ago he had taken the stand that these cases are probably of myopathic origin, due to some congenital defect in development, but in the light of modern investigation he is now disposed to believe that some central cause is operative—that there is a functional hereditary derangement of the central nervous system—a condition of lessened resistance in the cells. This does not seem to him a strange assumption, when one considers the well-known idiosyncrasies exhibited to various toxic influences. On the theory that some kind of toxemia is the foundation of this disease, he thought the observed phenomena could be explained—at least in this direction seemed to lie the possibility of solving the pathogenesis of this variety of disease. This patient had not been affected by the trouble until he was eighteen years of age; hence, there is no propriety in calling such a case "myotonia congenita." He divides these cases into three classes as follows: (1) myotonia congenita; (2) myotonia acquisita; and (3) myotonia transitoria.

Dr. Frederick Peterson asked, why a theory of causation might not be founded upon chemic changes in the muscles? Changes in the structure of the muscles, he said, are known to arise—for instance, in connection with typhoid fever.

Dr. Herter thought that we must look to toxic agents as furnishing at least a clue to the causation of such conditions. The peculiar susceptibility to certain types of poisons, seen, for instance, in epilepsy, must be referred to peculiarities of the central nervous system. He would agree with Dr. Peterson that these cases do not seem to be of central origin, and that it is more probable that they arise from chemic changes in the muscles. To study this subject successfully, it would be necessary to inquire into the condition of the secretions and excretions at the time of the onset of the disease, and not after it had become chronic.

PACHYMENINGITIS HEMORRHAGIA INTERNA IN CHILDREN

was the title of a paper by Dr. C. A. Herter, in which he said that internal hemorrhagic pachymeningitis is usually considered to be a very rare condition in children, yet one German observer has found it in about seventeen per cent. of his autopsies. The following cases were reported:

Case I.—A female child, five and one-half months of age, was admitted to the Babies' Hospital, May 15, 1897, with an entirely negative family history. The illness had begun one month previously with persistent vomiting. The head was of normal shape, and the fontanels were not bulging. There was a soft spot over one parietal bone. The child had no teeth. On the fifth day after admission tremor and nystagmus developed. Four days later there was a general convulsion, in which the mouth deviated to the left. Cyanosis was a feature of the convulsion. A second attack occurred within ten hours. After these seizures the fontanels were sunken. The child now became semi-comatose, and died after a few days. The autopsy showed the presence of hemorrhagic pachymeningitis, fibrinopurulent pleurisy, pulmonary congestion, fatty liver, and nephritis. Along the superior longitudinal fissure, over the entire base and over the island of Reil on both sides was a membrane covering the pia. The ventricles were normal in size, and contained about one dram of hemorrhagic fluid. There was fluid blood in all the sinuses. The cervical cord showed the same conditions. Under the microscope the right occipital region showed the pia attached to the cortex in many places, and there was a splitting up of the membrane overlying the cortex into two or more layers. The inner layer was infiltrated with small round-cells. The outer membranous layers consisted of the same cells, fibroblasts, and connective-tissue fibers. The island of Reil showed the same condition, but much more marked, as was also the case over the cerebellum. In the spinal cord there were only slight traces of hemorrhage.

Case II.—Female infant, colored, twenty-two months old. The child had been nursed seven months. It had never walked or stood alone, and was very rachitic. The first two months in the hospital were marked by slight loss in weight and considerable prostration. In October, 1897, the child was readmitted, with the statement that she had been well up to three days before, at which time she had had four convulsions followed by three more the next day. The general condition was very bad. The hands and feet were in a position of persistent flexor contraction, characteristic of tetany. The knee-jerks were unobtainable; the fontanels were bulging. There was slight, but varying rigidity of the muscles at the back of the neck. Bloody mucus diarrhea was present, and the child died comatose. The autopsy showed pachymeningitis hemorrhagica interna, bronchopneumonia, and acute and chronic ulcerative colitis. Over the right side of the brain was a recent blood-clot covering the entire hemisphere, and also the left occipital lobe. The inner surface of the dura was covered with a membrane extending from the superior longitudinal fissure on either side. The pia was congested. The ventricles and brain substance were apparently normal. All the sinuses were filled with recent clots. The microscopic examination showed thickening of the pia over the right temporosphenoidal lobe, and the vessels of the pia were thickened. There was also a thick membrane splitting up into layers, as in the other case. There were numerous small blood-vessels, and hemorrhages had occurred into the meshes of the membrane. In places, there were aggregations of small round-cells undergoing fragmentation. They were chiefly found in the superficial layers of the membrane. In the dura the fibers were separated from each other by serous infiltration, and the dura was covered with a membrane similar to that already described. In places, there was very extensive pachymeningitis.

It is at about the age of five months, the speaker said, that this disease is especially frequent. The majority of these infants are badly nourished, many of them being subjects of rachitis or of chronic colitis. The new membrane must be regarded as originating from proliferation of the dural endothelial cells. In some cases there is lit-

tle inclination to hemorrhage. The membrane is very variable in thickness; sometimes it reaches a thickness of two or three lines. There seems no good reason for thinking that the locality of the pigmentation indicates that the layer of blood originates from the inner surface of the dura. On the other hand, there is no conclusive proof of the old notion that the disease is of inflammatory origin. It is so common to find severe intoxications without such lesions that the intoxication theory does not seem tenable. It is apparently impossible to recognize the condition until the hemorrhage has occurred, and even then it is extremely difficult to make a positive diagnosis. Slight cerebral symptoms are probably masked in these very young and usually marantic children. The hemorrhage is probably more often unilateral, and the usual symptoms present are rigidity, hemorrhage, and coma. Paralysis is rarely noted. The pyrexia is usually less than in meningitis, but these cases are so commonly complicated with other diseases that the range of temperature is variable. The speaker did not think there is any symptom or combination of symptoms in hemorrhagic internal pachymeningitis which might not be encountered in any acute infection without any cerebral affection being present; but whenever unilateral rigidity and convulsions with deepening stupor are present in a cachectic or rachitic child under one year of age, we should think of such a diagnosis. It is probable that relatively slight traumatisms to the head may occasion rupture of the vessels in the highly vascular membrane. This gives these cases a certain medico-legal importance.

DR. PETERSON remarked that the condition is interesting to him because of the possibility of its being occasionally found in infantile cerebral palsy.

DR. HERTER said that he was inclined to think that these membranes are considerably more frequent than one would suppose from the literature. It is quite possible to overlook the presence of the membrane if it is not decidedly vascular.

A paper, entitled

THE PATHOLOGY AND MORBID ANATOMY OF HUNTINGTON'S CHOREA, WITH REMARKS ON THE DEVELOPMENT AND TREATMENT OF THE DISEASE,

was read by DR. JOSEPH COLLINS, who said that the neurologist frequently encounters knotty problems, and among these none had the secret of its genesis more carefully concealed than the hereditary degenerative diseases. The pathogenesis of the acute inflammatory diseases of the nervous system is an open book, but the degenerative diseases are discouragingly slow in yielding the mystery of their being. This is especially true of such degenerative affections as the hereditary ataxias, choreas, and dystrophies. The status of the original lesion cannot always be inferred from a consideration of the lesion found at the time of death, and this is particularly true if the disease has existed a great number of years. No one could do much laboratory work on the central nervous system of individuals who had succumbed to degenerative nervous diseases of long duration without having forced upon him the fact that there are certain abnormalities of the circulatory system—varying degrees of degeneration of vessels, changes in the size of the lymph spaces, and relative disproportion of connective tissue to the parenchyma—which occur in all degenerative diseases, considered entirely apart from their causation. He is convinced that such changes are very often secondary, and have no other significance than as evidences of protracted disturbance of nutrition, and that this nutritional depravity is the result of the existence of the original lesion. There is nothing more certain than the occurrence of glia proliferation in all slowly progressing, destructive lesions of the nervous system, but nothing can be more misleading than to consider this glia overgrowth to be primary, and the changes in the parenchyma secondary.

Huntington's chorea, Dr. Collins said, is a comparatively rare disease, and of rather recent recognition; hence, the reports made upon its pathology have not been uniform. The discrepancies are apparently the result of the varying points of view of different observers. In studying the nervous system in cases of Huntington's chorea it is scarcely justifiable to maintain that all the morbid conditions are inherent to the disease; for, as had been said, many of them might be the consequence of prolonged interference with nutrition. Although the present study of the pathology of the disease is upon an individual who has had the disease a considerable time, it is compared with a case of much shorter duration reported by Dr. C. L. Dana. A study of these two cases, he felt confident, would go far toward establishing the morbid anatomy and hinting at the pathogenesis. His patient was a man, fifty-five years of age, who had married in early manhood, and who was the father of three children—all of them giving evidence of neuropathic inheritance. The known duration of the disease in his case was ten years. In the beginning the hands only were affected, but in the last years the lower extremities were also involved. The mind remained in fairly good condition up to about three years before his death, when he began to have suspicions about his relatives and friends, and became forgetful and suicidal. His speech was so imperfect that during the last years of life he was understood with difficulty. Dr. Collins had seen him for the first time a few days before his death. He then had a temperature of 105° F., and it remained at about this point until the end. The movements were very severe and incessant, except during sound sleep, although even then they frequently wakened him. He was was quite conscious, but made no response to questions. The cause of death seemed to be exhaustion and high temperature. The disease was traceable to the maternal grandfather, an Irishman, who had three children, two of whom were similarly affected. One of these was the mother of this patient, and of her seven children, five were so afflicted. The other daughter had two children, one of whom became choreic. In three generations there had been no less than nine affected individuals, and when it was considered that many of these children died in infancy, the number of cases that had developed was surprisingly great.

At the autopsy, on opening the skull, the dura was quite adherent, the diploe dense, and the Pacchionian depressions marked. The brain had a wet appearance, as

did also the cord. The pia was not adherent to the brain. The convolutions of the anterior pole of the brain were very small, and the entire encephalon weighed forty-two and one-half ounces. The dura was intimately adherent to the spinal column. The principal fissures were somewhat wider, more shallow, and shorter than in the normal brain, but there was nothing pointing to defective convolutions. The average thickness of the gray matter was uniformly less than the normal, but this thinness could not be attributed to age. An examination of the pons and medulla oblongata did not show any marked variation from the normal, but the changes were more noticeable lower down. Microscopic changes were not confined exclusively to the Rolandic region, but the process here was more advanced. The specimens were stained by various methods, and carefully examined. The macroscopic changes were briefly as follows: (1) thinness and atrophy of the cortex; (2) the mottled, streaked appearance and cribriform state on cross-section of the brain, due to diminution in number and in health of the ganglion cells, and to the increased perivascular and pericellular spaces and increased patency of the blood-vessels. The microscopic changes were: (1) a decay or slowly progressive degeneration of the ganglion cells of the cortex throughout the brain, especially of the two deepest layers, the layers of large pyramids and polymorphous cells. This cell death was particularly evident in the Rolandic region, very much less so in the anterior pole of the brain, and incomparably less in the posterior pole; (2) increase of glia tissue, but not sufficiently prominent to constitute sclerosis, the conspicuous increase being about the blood-vessels and ganglion cells; (3) enlargement and distention of the pericellular spaces; (4) slightly diseased blood-vessels, consisting principally of a proliferation of the nuclei of the adventitia and a thickening of the intima. This involvement of the vessels was not regular or symmetric, but showed itself only in certain sections of vessels; (5) relative paucity of the medullated fibers of the cortex. In short, it might be said, that the lesion was a chronic parenchymatous degeneration of the cortex, with consecutive and secondary changes in the interstices, the brunt of the disease having been borne by the motor regions. There was, in consequence, a degeneration of the pyramidal tracts in the spinal cord. In Dr. Dana's case the central convolutions suffered most, and the process occurred in patches throughout the affected cortex. There was nothing to justify the opinion, that it was an inflammation—the process was evidently one of degeneration.

In connection with the treatment, Dr. Collins said, that he desired to emphasize the necessity for delaying the advent of the disease in those who had a hereditary tendency to it, and also to emphasize the folly of tenotomy of the eye muscles—a method of treatment now being carried out upon one of these unfortunate individuals in this city, with a promise of a cure. If we wished to influence the course of hereditary chorea after it had once become manifest, it would be necessary to administer whatever drug was selected in the largest possible doses consistent with life, and to maintain this medication for a long time.

DR. ONUF said that he had been present at the autopsy on the case reported in the paper, and had been especially impressed with the general narrowing of the gyri—a general atrophy. On section, the mottled condition of the cortex had been most striking, but the cribriform appearance produced by the enlargement of the perivascular spaces was also worthy of note. The general appearance of the brain resembled very closely that of general paresis. The microscope confirmed the macroscopic findings, although the changes were not as marked as one would have expected from the gross appearance. The cell changes were of the atrophic order. The characteristic feature was the accumulation of neuroglia cells in the pericellular and perivascular spaces. His impression was, that this accumulation is due to a secondary process following atrophy of the cells. The disease is evidently a degenerative one, originating in the parenchyma of the brain, and not in the interstitial tissue.

THERAPEUTIC HINTS.

The Tonic Effects of Zincohemol.—This remedy is said to be very efficient in increasing the quantity of hemoglobin in the blood, and maintaining the percentage attained. It is recommended by CERVELLO and SAVOCA in the following combinations:

For anemia and chlorosis:

℞ Zincohemol, Ext. gentianæ } aa . . . gr. lxxx.

M. Ft. pil. No. LXXX. Sig. Two to four pills three times daily.

For chronic diarrhea:

℞ Zincohemol, Ext. hæmotox. } aa . . . 3 iss
Glycerini, Aq. dest. } aa . . . . q. s.

M. Ft. pil. No. LXXX. Sig. Two to four pills four times daily.

As a sedative nervine in chorea and hysteria:

℞ Zincohemol, Ext. valerianæ } aa .. . . gr. lxxx.

M. Ft. pil. No. LXXX. Sig. Two or three pills three times daily.

Suppositories for Bleeding Hemorrhoids.—

℞ Ferri subsulph. . . . . gr. iii
Plumbi acetat. . . . . gr. i
Mass. hydrarg. . . . . gr. ss
Ol. theobrom. . . . . q. s.

M. Ft. suppos. No. 1. Sig. Insert one suppository morning and evening.

For Catarrhal Jaundice.—

℞ Ammon. iodi. . . . . 3 i
Liq. potass. arsenit. . . . . 3 ss
Tinct. calumbæ . . . . . ℥ ss
Aq. dest. . . . . 3 iss.

M. Sig. One teaspoonful three times daily before meals.

ORIGINAL ARTICLES.

SOME OF THE VAGARIES OF CROUPOUS PNEUMONIA.[1]

BY HENRY L. ELSNER, M.D.,
OF SYRACUSE, N. Y.;
PROFESSOR OF THE SCIENCE AND ART OF MEDICINE AND CLINICAL MEDICINE IN THE SYRACUSE MEDICAL COLLEGE.

THE deductions presented in this paper are the result of a careful consideration of 150 cases of pneumonia observed in private, consultation, and hospital practice. It occurred to the writer as he examined the records of these cases that it might be of interest to the profession to learn something of the peculiarities of croupous pneumonia as seen in Central New York.

I was surprised to find many cases in which, at some time during the course of the disease, unusual features presented, frequently making a positive diagnosis impossible, and at other times obscuring the diagnosis of pneumonia which had already been made.

The pneumonia of Central New York may be considered the most typical disease of an infectious nature which the physician is called upon to treat. In eighty per cent. of our cases the characteristic chill and fever and all of the other usual symptoms followed each other in regular order, the disease running a typical course within from six to eleven days. In twenty per cent. of our cases, however, there were vagaries which occasionally masked the diagnosis. In these, careful and acute diagnosticians were puzzled during the period which preceded the appearance of characteristic objective and subjective signs.

The 150 cases may be tabulated as follows:

TABLE I.

[1] Read at the last meeting of the American Climatological Association.

The right lung was involved in sixty per cent. of the cases; the left lung in twenty-four per cent.; both lungs in sixteen per cent. The localization of the disease in the various parts of the lungs corresponded very closely with that given by Jurgensen, Grisolle, Busse, and other voluminous writers on this disease. There were twelve cases in which the apex was involved; in seven of these the right apex was diseased; in five, the left.

It may be remarked in connection with *apex-pneumonia* as we see it in Central New York, that, as a rule, it is not associated with active cerebral symptoms which would justify us in speaking of it as synonymous with cerebral pneumonia. Indeed, the majority of these cases presented less delirium than was true when other parts of the lung were involved, and most of them were marked by a typical course, terminating by crisis without further complication. Those forms of mixed infection in which active pneumonia attacks a tuberculous apex are not included; attention will be directed to them in another place. One of the apex cases was a traumatic pneumonia in a boy eleven years of age, who had sustained a fracture of the skull three days before the onset of the disease; his mind was at all times clear, and he made a full recovery.

In fourteen per cent. of the cases in adults the initial chill was absent. This was commonly observed in cases of pneumonia occurring in alcoholics or in aged and enfeebled subjects, and in most of the severer forms of the disease occurring in children. It is rare to find evidence of the occurrence of a chill in the subjects of croupous pneumonia previous to the tenth year of life. The disease is more frequent in early life than it was formerly supposed to be. In a number of our cases of secondary croupous pneumonia, particularly that associated with or following other infectious disease, the chill was absent, the first evidence of the disease being a marked increase of the already existing fever, with an increasing frequency of respiration. In such cases positive physical signs were absent for from one to three days; the symptoms of the primary infection were intensified, there being present a true typhoid condition and characteristic sputum, while the objective symptoms followed on the third or fourth day of the pulmonic affection.

In thirty per cent of the *influenza-pneumonias* of the croupous variety the disease developed gradually

after a period of malaise accompanied by the usual symptoms of the primary affection. Seventy per cent. of the influenza-pneumonias were ushered in with a well-defined chill, severe but characteristic of the ordinary form of the disease. When this occurred we found that the pneumonia was of much shorter duration than in those cases in which the chill was absent; that it was associated with a more sthenic condition of the patient, and gave a decidedly better prognosis. In a few cases of this type we were surprised to find large areas of consolidated lung tissue, sometimes remnants of recent pneumonias, without marked subjective symptoms, but with positive physical signs, in which the condition had not been suspected. Many of these cases dragged along during a number of weeks with but little sputum, although, at times, there was marked rusty sputum during a day or two. During the later weeks, the sputum usually became mucopurulent, nummular, and finally disappeared as gradually as did the physical signs. Most of these patients made a full recovery. Microscopic examination of the sputum showed the presence of the pneumococci of Fränkel and Friedlander and frequently streptococci in abundance. It may be readily understood that these cases aroused a suspicion of existing tuberculosis. The microscope served to differentiate this latent form of pneumonia from the tuberculous infection which we have learned to fear as a complication or sequel of *grippe*.

No cases were more difficult to diagnose than were those of *central pneumonia without chill* occurring in children, occasionally in adults, with marked gastric symptoms, slight jaundice, abdominal distress and pain. In many of these there was but little cough during the first twenty-four hours, hurried respiration and a continuously high temperature being the only accompanying symptoms. The physician who has had much to do with croupous pneumonia occurring during early life, has learned from his experience to be suspicious of its presence when persistently rapid respiration and elevation of temperature are present, even though other marked pulmonary symptoms of a subjective or objective character are not manifested. Abdominal pain misled a number of physicians with whom I saw these cases, and when this was associated with slight jaundice, central pneumonia was not suspected. In the case of a child five years old, with the symptoms just mentioned, we found tympanitic resonance over the lower lobe of the left lung persisting for two days without other physical signs, save bronchophony over a small area. Gradually it became evident that a central pneumonia was spreading toward the surface; bronchial breathing with crepitant râles became clear, and the child died after a three-weeks' illness with every portion of both lungs consolidated.

The method of Leube, in which, in such cases, he searches at an early stage for an area of bronchophony, and in which after twenty-four or thirty-six hours he has found confirmatory signs of the disease, such as bronchial breathing and crepitant râles, has often proved an important aid, but it, too, has occasionally failed. It may be safely concluded that the cases of pneumonia characterized by absence of chill were, as a rule, of the asthenic variety; that they ran a protracted course, rarely terminating before the eleventh or thirteenth day, usually by lysis, and in a large number there was an alarming typhoid condition which developed during the fourth or sixth day and was evidenced by profound nervous symptoms, muttering delirium, considerable albuminuria, feeble and rapid pulse, death usually ending the scene with less evidence of carbonic-acid poisoning than was present in the equally serious sthenic cases of the disease.

Among the noteworthy pathologic features presented in this asthenic type of pneumonia may be mentioned an ultimate though diffuse infiltration of the lung. Several foci were usually found, and the inflammation was prone to attack both lungs. The stage of red hepatization was short, the lung tissue was soft, tore easily, and there was a great tendency to puriform infiltration. The spleen was enlarged. In a number of these cases pleurisy appeared at an early stage, usually serous, sometimes purulent, but it was not at all uncommon to observe the occurrence of empyema after serous pleurisy. Among the other complications, kidney involvement was common, and in a few cases endocarditis, pericarditis, or meningitis, were the final concomitants. There can be no doubt that these forms of asthenic pneumonia without chills are increasing, and that the greater mortality of pneumonia in many sections of this and other countries is very largely due to this fact.

Another variety of pneumonia to which I wish to call attention, and which is among the more difficult forms of the disease to diagnose, is the one presenting *the symptom complex of an acute meningitis*. In such instances there was not a single physical sign or subjective symptom to call attention to the lungs, but there was present a clear picture of meningitis, often without respiratory embarrassment. In these cases the deep involvement of the brain is due to pneumococcic toxins. In some of these we found *post-mortem* a limited area of lung tissue involved, usually central, without a single lesion or change in the brain to account for the symptoms during life. These cases are not uncommon.

Three instances of *afebrile pneumonia* were ob-

served in patients aged respectively sixty-five, sixty-seven, and seventy-four years. The first example of this type occurred without any prodromata or initial chill, but all the characteristic physical signs of the disease were presented, the lower lobe of the right lung being involved; there was rusty sputum. This patient had suffered many years from interstitial nephritis accompanied by polyuria, a moderate amount of albuminuria, tense pulse, and arteriosclerosis. The disease terminated favorably by crisis on the sixth day, although the crisis was followed by an alarming condition of the patient, which continued, with profuse perspiration, almost twenty-four hours; the patient ultimately rallied, living six or seven years after his recovery and finally dying of uremia.

The subject of the second case was also an albuminuric, with less marked arteriosclerosis, but with evidences of secondary contracted kidney. The patient died on the fifth day of the disease. The diagnosis was confirmed by autopsy. One-half of the left lung was found to be completely consolidated, and there was positive evidence of the presence of the second stage of croupous pneumonia. The heart was hypertrophied in all directions, and the kidneys had undergone secondary contraction.

The third patient had been previously healthy, had no evidences of renal or cardiac disease, but had been subject to great nervous strain and was in a very much reduced mental and physical condition during the two or three weeks preceding the onset of the disease. The case terminated favorably by lysis.

All of these patients were well nursed, carefully watched by trained attendants, and the temperature taken four times daily. In none did the latter at any time go above 100.1° F.

There seems to be an antagonism between the pneumococcic toxins and blood which is surcharged with urea, or changed as the result of chronic nephritis. This fact has been observed by a number of writers, and we are at the present time carrying on experiments to determine whether this conclusion is justifiable. It may be still further asserted that in all of the cases of afebrile pneumonia which the writer has observed there has been great nervous depression. In several cases there was an afebrile period, varying from one to three days, during which there was progression of pneumonic infiltration without preceding chill. On the third or fourth day the temperature began to rise gradually, reaching its maximum about the sixth day, the disease ultimately becoming asthenic. Death followed in the majority of these cases between the tenth and fourteenth days, with rapid pulse, but without evidences of carbonic-acid poisoning. In these we did not find preceding albuminuria, but the patients were much reduced in strength and nerve force before the advent of the fatal affection.

Hyperpyrexia was frequently found in the sthenic forms of the disease. We observed it more frequently in hospital than in private practice. In fifteen hospital cases the temperature rose above 105° F. in five. In one of these the temperature reached 107.5° F., remaining there almost twenty-four hours before death occurred. In two in which recovery occurred, the temperature reached 106.2° F.; in private practice, in 135 cases, the temperature rose above 105.5° F. in only ten, seven of which occurred in children. With corresponding involvement of lung tissue, it may be assumed that the temperature in children ranges from one and one-half to two degrees higher than in adults.

Among the unique clinical manifestations observed was a condition to which the writer gave the name "*post-pyrexial* delirium" a number of years ago. Since reporting my first case with this characteristic I have noticed a number in medical literature, all presenting about the same features. Four such cases are included in the collection. In all the disease had been of sthenic variety. The febrile period averaged six days, during which the patients were unusually clear-headed. *Following the crisis* in from three to ten days, these patients became the subjects of active and wild delirium during which they were restrained with difficulty—a true "delirium-ferox," without the slightest increase of body heat. In three such cases the period of delirium continued between seven and twelve days, in the other, the patient was wildly delirious during two weeks, then merged into an irresponsible condition in which she was easily controlled, making a final recovery after the fifth week. The writer does not include in these cases of post-pyrexial delirium those forms of insanity and nerve depression which sometimes follow influenza, for in the majority of such cases there usually was more delirium during the active period of the disease than during the period of convalescence, and finally, the train of nervous symptoms which persisted weeks and months, at times leading to permanent insanity.

Among the vagaries of pneumonia, a peculiar behavior of the pulse in the subjects of *arteriosclerosis*, with or without manifest renal complication, has occasionally been noted. During a period varying from two to four days, the pulse remained tense and slow, rarely being above eighty per minute. After this period, the tension became suddenly lowered, the pulse rapid, irregular, and intermittent, and the patient died with all of the evidences of cardiac asthenia on the fifth or sixth day of the disease. Ex-

perience has taught that this period of calm and slow pulse in the subjects of arteriosclerosis, is something to be feared, for it almost invariably leads to a fatal termination, preceded by a sudden lowering of arterial tone and almost immediate cardiac failure.

Ambulatory pneumonia is rarely observed in Central New York. In the cases reported there was only one in which the diagnosis was made positive by *post-mortem* examination. This case occurred in a man forty-two years of age in whom the disease existed four days, during which time he was up and about. He died within twenty-four hours after his admission to the hospital. The *post-mortem* showed the right lung to be entirely solidified, well advanced in the second stage of the disease, and marked edema of the left lung; the right half of the heart dilated with a large thrombus extending into the pulmonary artery.

Among the cases of *malignant pneumonia* are three which occurred in one family within one week of each other. All resulted fatally before the sixth day of the disease. The toxemia seemed over-powering, the local disturbances being subsidiary.

Traumatic pneumonias are comparatively frequent, particularly after serious head injuries, and it has been the writer's experience to find the larger number during early life. In children this type is almost always fatal.

Aspiration, or the "*Schlück pneumonia*" of the Germans, was observed three times. Two cases resulted in recovery. The disease was protracted, and complications, particularly edema of the lungs, were not unusual. The only case of pneumonia which followed the inhalation of ether was that of a woman whose breast had been amputated for cancer. The disease was of sthenic variety; there was a chill within twenty-four hours after the operation; the disease was severe, but ended favorably by crisis without interfering with the primary union of the wound.

An annoying complication of *senile pneumonia* was the blocking of the bronchial tubes with retained mucus, with ultimate collapse of air-cells, all of which masked the physical signs of pulmonary infiltration.

In spite of the fact that several cases were seen in which there was a characteristic intermittent fever, with at the same time advancing lung involvement, there were no data, microscopic or clinical, which justified the assumption that there was present an added malarial infection. The administration of quinin in these cases failed to influence the fever in any way.

In three cases there was sudden and unexpected death; once during the period of convalescence; twice after crisis, when a favorable prognosis had been given. These deaths were in all probability due to the effects of the specific toxins upon the heart, and the accompanying acute myocardial degeneration. I do not include those cases in which there had been preceding nephritis, or organic heart disease. In this connection it may be added that the toxemia is by far the most important element to be taken into account in considering the treatment and prognosis of pneumonia, and it is certain that in the majority of cases it stands in no relation to the extent of lung tissue involved. Limited areas of disease have often been associated with more profound evidences of infection than was the case with far-reaching consolidation.

Eighty-five and one-half per cent. of the cases terminated by crisis, and 14.5 per cent. by lysis; the crisis occurred in the majority between the fifth and eighth day of the disease; in one it occurred on the thirteenth. The longest-deferred crisis was noted on the fifteenth day. It was not uncommon to have the fever continue with but slight change until the eighth or tenth day, when crisis occurred. The old notion of the ominous uneven days is not justified. Persistence of fever after the eighth day without positive evidence of fresh involvement of lung tissue or other discoverable complications must lead to the suspicion of tuberculous disease. A sharp rise of temperature during the twenty-four hours preceding the crisis was not uncommon. A decided rise of temperature following crisis, sometimes three or four exacerbations, alarmed many physicians who were not warned of the possibility of such an occurrence. In twenty-four cases there were pseudo-crises. These occurred, as a rule, between the fourth and sixth days; the earliest was observed on the third, the latest on the twelfth day. After the crisis, and during the period of convalescence, it was not uncommon to observe one or two sharp rises of temperature without accompanying leucocytosis, or other demonstrable complication.

The majority of cases of croupus pneumonia showed a *marked increase of the polynuclear leucocytes* during the febrile period, with a reduction as the temperature declined. In thirty cases in which we made blood counts there were evidences of leucocytosis in twenty-two. The greatest number of white corpuscles were found immediately before the crisis. In all cases examined within thirty-six hours after crisis there was no further evidence of leucocytosis. As a rule, there was no reduction during pseudo-crisis; in two cases an increase of leucocytes was observed. The occurrence and intensity of leucocytosis may be said to depend almost entirely upon the virulence of the pathogenic micro-organism causing the disease. This clinical fact is em-

phasized by the result of animal experimentation. It was impossible to demonstrate satisfactorily any relation between the extent of the disease and the existing leucocytosis. The malignant forms of pneumonia with far-reaching and rapid infiltration, also asthenic cases with or without extensive consolidation, particularly in those subjects who were poorly nourished, gave low average blood-counts. For differential purposes it may be concluded that the presence of leucocytosis in acute febrile disease favors the diagnosis of pneumonia; that its absence favors the diagnosis of typhoid fever or of a severe form of lung inflammation; that marked leucocytosis favors the diagnosis of croupous pneumonia against purulent pleurisy; that the presence of leucocytosis is a favorable, but by no means certain, prognostic sign.

From the cases here considered I conclude that the *fully developed physical signs* which justify a *positive diagnosis of pneumonia are rarely present before the end of the second day of the disease*, and it is not infrequent to see the third day pass without the development of the characteristic breathing and râles. I have notes of several cases in which, with fully developed physical signs, there was no expectoration. The expectoration was typical in the majority of cases, but it, too, was often atypical in color, consistency, and quantity.

It would draw this paper to too great length if all the complications observed were considered. Without going into detail it may be said that following heart weakness, edema of the lungs was one of the most serious disasters. The various serous and purulent effusions were usually successfully treated. In one case the disease was complicated with abscess of the lung, and the pus was finally located after seven unsuccessful explorations with the hypodermic needle. The abscess was opened and drained, and the patient made a perfect recovery. Albuminuria was present at some time during the course of the disease in over ninety per cent. of the cases; in ten per cent. of these there were evidences of nephritis.

In considering the clinical material, those forms of mixed infection which have been brought to light by the bacteriologic study of the cases cannot be ignored. Under this head are included those cases of tuberculosis which were accompanied by inflammatory processes in the lung caused by the concurrence of two or more infecting agents, one of which was the tubercle bacillus. The fact has been repeatedly demontrated, experimentally and clinically, that the tubercle bacillus alone, without the presence of other infecting agents, has the power of causing changes in the lung which simulate very closely the various forms of acute and non-tuberculous pneumonia. Clinically, such cases are necessarily differentiated with great difficulty, and require repeated microscopic examination of the sputum (the centrifuge aiding materially) before a positive diagnosis can be made. It is possible to have two pathologic processes in many cases of pulmonary tuberculosis; one leading to the formation of tubercle, the other giving rise to pneumonic infiltration.

These cases I have classified as follows:

1. Cases of acute fibrinous pneumonia, in which the disease attacks an area of lung tissue, the greater part of which is the seat of infiltrating, but latent, tuberculosis. The previous history includes disease in a distant organ, from which pulmonary tuberculosis took its origin, or with which it was coincident. The latent pulmonary deposit, as a rule, did not give rise to subjective symptoms before the advent of the acute pneumonia.

2. (*a*) Cases in which there is an acute croupous or catarrhal pneumonia in the immediate vicinity of tuberculous areas, the latter previously recognized, with changes in the infiltrated areas, usually at the apex, the fibrinous disease running its course and terminating by crisis or lysis. This type is not associated with hemoptysis as a prodromal or initial symptom. (*b*) Cases of chronic or subacute pulmonary tuberculosis in which acute catarrhal or croupous pneumonia attacks distant areas of the diseased or opposite lung, in which there is no early hemoptysis, but in which the tuberculous process is actively progressive, with physical signs of beginning or already completed disorganization.

3. Cases which may be called streptococcus-pneumonia, in which the disease is added either to a latent or an active pulmonary tuberculosis. Hemoptysis is present, usually, during the early stage of the acute exacerbation, or immediately precedes the pneumonia. Here the complication depends largely upon the aspiration of infecting agents from the seat of the original infiltration and ultimate disorganization.

4. Cases of acute catarrhal, occasionally fibrinous, pneumonia with concurrent infection, when, as a result of lowered vitality, resulting usually from child-bearing, alcoholism, or unfavorable environment, there is, in a comparatively short time, rapid disorganization of lung tissue, ultimate cheesy infiltration, with the clinical evidences of coagulation-necrosis, hectic fever, and finally death.

The most unique and at the same time surprising cases of mixed infection which have come to my notice, are those in which there has been no suspicion of existing pulmonary tuberculosis antedating the accompanying pneumonia. There were no lung symptoms until the violent outbreak of croupous disease, and in no case which I have seen had the physi-

cian been consulted to prescribe for or examine the patient. The general appearance had, in many cases, been so good that during the early days of the acute pneumonia no suspicion of the true state of affairs was entertained, and not until it became plain that the pneumonia was not following a typical course and bacteriologic examinations were made, were the facts established which made it positive that a mixed infection was present. In the majority of these cases the added element gave rise to a croupous pneumonia which involved the area of latent disease and the tissues immediately adjacent to it.

While there are in many of these cases no subjective complaints, or objective symptoms of pulmonary tuberculosis before the appearance of pneumonia, careful inquiry and a thorough search reveal the fact that there have been foci in distant organs, from which pulmonary tuberculosis proceeded, or with which it was originally closely related. Many of these patients present good family histories, while their personal record strengthens the conclusion that lung tuberculosis may be present, but dormant, awaiting the advent of some depressing agent or added pulmonary disturbance. In other words, lower by the addition of the second germ the resisting power of the patient who has an unsuspected tuberculosis, and, as a rule, the result will be tissue disorganization and consequent progression of the original disease. I know that this conclusion is contrary to the belief of many who attribute to mixed infection little influence on latent tuberculosis, and who prognosticate favorably in cases of this class, but I give it as being in accord with my own clinical experience.

SCHOOL HYGIENE: LIGHTING OF SCHOOL-ROOMS AND ITS RELATIONS TO ANOMALIES OF REFRACTION.

By J. A. BACH, M.D.,
OF MILWAUKEE, WIS.

It is a well-known fact among oculists that nearly all eyes at birth are far-sighted. As the general development of the body proceeds, the eyes approach nearer and near to the normal, and under certain conditions the relative length of the anteroposterior axis of the eyeball may, by the stretching following abnormally rapid growth, go beyond the normal and produce near-sightedness. Unequal curvatures in the different meridians of the eye, especially of the cornea, produce astigmatism. This condition, with a few exceptions, is always congenital.

Persons whose occupations do not necessitate close vision, such, for instance, as may be found among the Indians, rarely lose all their far-sightedness during development, and as a class are a far-sighted people. On the other hand, it is the oculist's daily observation that persons who apply themselves to close work from childhood, as a rule, not only lose their far-sightedness, but a very large percentage of them become near-sighted in varying degrees. Especially is this true when the conditions are such as to necessitate a close approximation to the work under unfavorable surroundings. This tendency to the development of near-sightedness is most marked during the years of active growth, when the tissues are soft and unresisting. Any influences which produce an abnormal congestion of the eye with a consequent poor circulation in this organ, tend to favor the development of anomalies of refraction by lowering the resistance of the coats of the eye and increasing the intra-ocular tension. The result is that the organ will gradually yield at its weakest point—the posterior part—producing elongation of the eyeball, a condition constituting myopia.

Persistent use of the eyes in near work, thus strongly exercising the accommodation and convergence, is beyond doubt the chief immediate cause of the development of myopia. The lateral compression of the eyeball by its muscles, together with the congestion of the eye, resulting partially from the effort and partially from the stooped posture which is generally assumed during close vision, are responsible for a great deal of injury to the eyes. Close approximation to work and the consequent unfavorable conditions referred to can only be avoided by having proper and sufficient light, which becomes a source of the greatest relief to the eye already burdened with the effort to overcome any mechanical defect which may be present; the demand upon accommodation and convergence will be much lessened, as it enables the holding of work at a greater distance from the eyes. With proper light the retinal image becomes brighter and more clearly defined, and the ocular irritation resulting from the efforts for greater distinctness is distinctly lessened.

Light reaches the eyes in three different ways, as follows: (1) Direct light, or that which strikes the eye directly from its source. (2) Reflected light, or that which strikes the eye after it has been thrown back by one or more surfaces sufficiently smooth to reflect a considerable number of rays in the same general direction. (3) Diffused light, or that which reaches the eye after it has been reflected from all possible surfaces round about. In diffused light the air is crowded, as it were, with silent lines of light. Back and forth they pass in all directions, every surface receiving light, every little grain and fiber acting as a reflector to send it out again. Thoroughly diffused light does not cast shadows, all surfaces participating in reflection and re-reflection.

The most favorable light, as to quantity and qual-

ity, to work by is the diffused white sunlight from a northern sky. Using this as a basis, we must further consider the direction from which this light is admitted for use, so as to avoid annoying reflections and other disturbing elements. It will be seen that the question of light may be considered under three heads, *viz.*, quality, quantity, and direction.

Quality.—White sunlight is the normal stimulant of the retina, and any light which does not at least nearly correspond in composition with sunlight is defective by just so much, and may become a source of fatigue. Many schoolrooms through the entire day, and nearly all rooms for a portion of it, have no direct sunlight, and all the light they receive is entirely by reflection. Of this the portion coming from surfaces on the earth, etc., is a very considerable part. Light-colored surfaces are the most valuable reflectors, as they least disturb the composition of sunlight, and, at the same time, reflect the largest number of rays. It becomes, therefore, a matter of no little importance to see that the surroundings of school buildings be as free as possible from colored reflecting surfaces. Each substance has its effect upon the light which it reflects; some of the light is absorbed and that which is reflected carries with it the effect of color characteristic of the reflecting object. Again, surfaces may be illuminated by colored light depending upon nearby surfaces. Thus, conditions occur when there will be very noticeable flushes cast over the pages of the books of school-children and which may be easily traced to the predominating influence of some one of the reflecting surfaces.

Concerning the function of light when it finally reaches a room, it may be said that that which passes directly from the window to the eye is of no benefit, except as it enables one to see the outside view. After the light passes into the schoolroom it is reflected back and forth between walls, floor, furniture, and occupants. The light which these various surfaces reflect gives impressions of form and color by which we appreciate objects. To preserve the light as pure as it entered, it will be readily seen that colored surfaces in a schoolroom should be avoided. A neutral gray, or such a shade of gray as may be necessary to modify the light in a room, should be used on the walls, curtains, and other reflecting surfaces. This, containing all the elements of white light, does not disturb the composition of light, and yet enables a variation of the amount of light by varying the degree of the color of the window-shade.

Quantity.—The darkest place occupied by any pupil should have at least sufficient light so that he may, without special effort, on account of insufficiency of light, read diamond type at a distance of at least twelve inches from the eye. By diamond type I mean the smallest type used by printers. The size of this type approximately subtends an angle of five degrees at a distance of twelve inches from the eye, and represents about the limit of distinct vision. This test is sufficiently accurate for practical purposes. The diffused white sunlight from the northern sky, in general terms, is a close approximation to the desired amount. It is more usual to err on the side of insufficiency of light than on the side of excess. Therefore, it is safe to allow as much desirable light as possible to enter the schoolroom. To facilitate this the school building should have full and free exposure to the sun in order that the most perfect source of light may be fully utilized, either directly or indirectly. Such buildings should, if possible, stand upon elevated ground of sufficient area to prevent any adjoining building or trees from casting interfering shadows. The windows should be large and should be equal to about one-fifth the area of the floor. As little space as possible should be occupied by divisions in the windows. The windows should reach to the ceiling, and no obstructing ornamental projections, either outside or inside, should exist. The best effect is obtained with square-topped windows, the Gothic style being objectionable. The regulation of the amount of light, especially in those rooms of a school which are exposed to the direct rays of the sun, is of great importance. Blinds and curtains are used for this purpose. The essential qualities which these light-regulators should possess are as follows: (1) They should intercept the direct rays of the sun. (2) They should not dazzle. (3) They should transmit a maximum amount of white light. It is, indeed, difficult to find material which perfectly meets all these indications, but this can be approximated by such material as will not interfere with the quality, nor yet too much with the quantity of light.

This we find in combining the extremes, black, or the absence of all light, and white, giving such a shade of gray as may be desired to meet the indications. Blackboards, although not disturbing the quality, absorb a considerable portion of light, and, if the general amount is not plentiful in a given room, these should not cover too much surface; such rooms, as well, should have the walls colored white or nearly so. The ceilings of all rooms should be white, as by this is gained a valuable diffuser and reflector of light. Glass dulled on one side by sand-blowing, and gray cathedral glass, make desirable substances for shading, but being too costly, are hardly practicable. Colored materials of whatever shade, except gray, should never be employed. Shades should roll at the bottom of the window; this will allow the more advantageous light to enter, be-

sides making it easier to lower the upper window for other purposes.

No artificial light can ever equal diffused sunlight, and, therefore, it is very desirable that children should be required to do their studying during the day if possible. However, when required, artificial light should be made to correspond as nearly as possible to natural light. It should be ample in quantity, good in quality, and come from a suitable direction. It should, furthermore, be steady, otherwise it will be dazzling and fatiguing. Experiments have been carried on by means of concave mirrors throwing the light to the white ceiling, thus diffusing it equally through the whole room, while the source of light remained hidden. The results are said to have been perfect. The electric light possesses an additional advantage over other artificial light, in that it does not vitiate the air—a very important consideration when large classes are confined to one room during a long period of time.

Direction.—The most favorable direction in which light can enter a schoolroom is probably from above. The photographer well knows the excellent service of diffused skylight. Unfortunately, however, school buildings are more than one story high, making this impracticable, excepting for the upper floor. All light that is not reflected directly from the work can only be a source of annoyance. If it is direct light which strikes the eye, the retina becomes unduly irritated, and cannot properly perform its function. Reflected light, as well, irritates the retina excessively, and often causes a confusion of the letters on the printed page with the images of other objects from which it may be reflected. For this reason blackboards should not be placed beween windows, as the direct light from the windows will be a source of the greatest danger to the eyes of the pupil using them. The surface of the blackboards must not be glossy, but rather a dull black to prevent strong reflections. Light coming from below the level of the work or the head of the child is often worse than useless.

It will be readily seen that light should enter from such a direction that it strikes the work from above and from the left side. Light from the right side is, as a rule, objectionable, because it casts shadows, and for the same reason light from behind is not desirable, shadows of head and shoulders being cast over the work, either reading or writing. To increase the general lighting effect, partially diffused light from behind, but from as high a level as possible, may be permissible. If the rooms are properly arranged, sufficient light from the left side may be admitted without resorting to other sources. It will be noted that the light as it comes from the left strikes the page, and most of it is reflected from the page at the same angle that it originally touched it. This light does not pass on as so much useless light, but as it passes from surface to surface, lighting the room from millions of reflections and re-reflections until finally becoming thoroughly diffused throughout the room, each nook and crevice is equally well illuminated with the general light in the room. This light being so strongly diffused does not cast shadows, is sufficient in quantity, and, if the reflecting surfaces are free from color, non-irritating in quality. It is the ideal light, and it has been amply proven that many, if not all the aggravating eye-strains and their varied consequences, so prevalent in our schools, could be avoided by close attention to this subject.

Bearing directly upon the well-being and health of the child's eyes as well as of his body is the position assumed during study. The seating of school children, therefore, becomes a subject of almost as great importance as the provision of proper light. A bad posture is not only injurious to the health of the eye, but is a fruitful source of curvature of the spine. Eulenberg says that ninety per cent. of curvatures of the spine, not induced by local disease, are developed during school life, and are directly traceable to improper seating. The improvement in American school-desks, as all know, has been great during the last few years, yet in many particulars we are far from perfection in this respect. As a rule, insufficient attention is being given to the size of the desks relative to the size of the children, and in many schools may be found desks all of the same size. As has already been pointed out under the subject of light, the great object in view is the prevention of undue approximation of the pupil to the work, and to avoid stooping. Desks should, therefore, correspond relatively in size to the size of the pupil. A back rest is necessary, but in nearly all desks this is too high, and interferes with the free movements of the body, besides encouraging a sliding down of the body. A good and substantial support to the pelvis and lower part of the back is sufficient and decidedly the least fatiguing. Furthermore, a child should rest the feet on a foot-board or the floor to sit easily. Non-support of the feet while sitting produces great fatigue and restlessness in children. The height of the seat, the height of the desk, and its slope are all very important. The slope for reading should be about 40°, and for writing 20°. The edge of the desk should at least come up to or slightly overlap the edge of the seat. This is an important consideration, and assists much in preventing the habit of stooping. It must, however, be borne in mind that, however important and necessary a proper school desk may be, it is equally essential

that the habit of correct sitting be acquired, and the teacher should dwell on this point at the beginning of the school year. Cramped and awkward positions are not likely to be assumed by an occupant of a properly fitting desk, except in writing and drawing, yet the habit of bad positions of sitting for all work may be acquired by the pupils unless properly instructed. Pupils should never approach their work closer than twelve inches.

It remains an undisputed fact among oculists that the constant stooping forward of the head and the close approximation to the page, is the most effective factor in the causation of myopia, save possibly constitutional predisposition. Eyes under these conditions are working in a state of tension, as it were, which, if long continued, produces a deep intra-ocular pressure, softening and stretching of the coats of the eyeball, and results, in milder forms, in a slight elongation of the eyeball characteristic of myopia. It has been noted with a great deal of satisfaction that whenever radical improvements in the lighting and seating of schools have been carried into effect, the reduction in the prevalence of myopia has been so great that its ultimate absolute prevention would seem a probability.

It must be observed, however, that not only must pupils be properly protected while in school, but the parents as well must cooperate, and the close application of the scholars at home under unfavorable conditions must be discouraged. After the child has attained its full growth, its tissues become more resisting, and injury to the eyes in the manner above stated, becomes less frequent.

CLINICAL MEMORANDA.

EXCISION OF THE RIGHT CLAVICLE FOR OSTEOSARCOMA.

BY GEORGE TULLY VAUGHAN, M.D.,
OF WASHINGTON, D. C.;
PASSED-ASSISTANT SURGEON, U. S. M. H. S.; PROFESSOR OF PRINCIPLES AND PRACTICE OF SURGERY IN GEORGETOWN UNIVERSITY.

W. S., American, aged twenty-eight years, was admitted to the marine ward of the German Hospital, Philadelphia, October 15, 1895. His family history was negative, and he denied all venereal diseases and rheumatism. During March, seven months before admission, he began to complain of pain situated in the right clavicle. Shortly afterward enlargement of the bone became apparent. The pain was of a dull aching character, often radiating to the chest and mastoid process on the right side, and was aggravated by use of the arm. On examination, the inner two-thirds of the clavicle was found to consist of a hard, spindle-shaped tumor, extending to within 2½ cm. of the joint. The right external jugular vein was distended.

October 22d, under ether anesthesia, the entire right clavicle, with the tumor, was removed by an incision extending along the bone from one end to the other, disjointing the acromial end first, dissecting the tumor loose from the surrounding parts, and last, disarticulating at the sternoclavicular articulation. The tumor was broken through while using the bone as a lever in separating its sternal attachments. To control the hemorrhage, it was necessary to apply over twenty ligatures. To prevent dropping of the shoulder, the detached portions of the trapezius and sternocleidomastoid muscles above were carefully sutured to corresponding portions of the deltoid and pectoralis major muscles below. The wound was closed with catgut sutures, leaving an opening in the middle for a gauze drain, and the dressing was applied, with the arm in the Velpeau position.

Subsequent to the operation, the highest temperature was 102.2° F., which continued for one day only.

FIG. 1.

Showing site of operation and resulting deformity after excision of the clavicle.

Fourteen days after the operation the patient was out of bed. The wound healed by primary union, except at two points, one in the middle and one at the outer end, which healed by granulation. Forty-one days after the operation the patient was discharged. There was no deformity and no interference with the function of the arm. The tumor measured 11.25 c.cm. in circumference, and, on microscopic examination, was pronounced a mixed-cell sarcoma. The accompanying illustration shows the condition of the parts one year subsequent to the operation, and it will be seen that there is absolutely no deformity except the absence of the clavicular prominence on the right side. During the interval he had been performing his accustomed work as fireman on a steamboat, and stated that he felt no inconvenience from the loss of the clavicle, his arm being free from pain and as strong as ever. With his clothes on there was no evidence of dropping of the shoulder, and after stripping it was barely perceptible—not more than one centimeter—which is no more than is often observed in the normal individual.

Excision of the entire clavicle seems to be a rare operation, though partial excision is comparatively common. Professor Ashhurst up to 1893, had been able to collect but 36 cases of the complete operation at one sitting, following which there were 7 deaths, a mortality of nearly 20 per cent. It seems that Dr. Charles McCreary did the first complete excision in 1813, removing the right clavicle from a boy of fourteen, with scrofulous caries; that of Remmer in 1732, given by Gross as the first operation, having been, according to Ashhurst, a partial excision. The same author gives the mortality from partial excision, or excision *a deux temps*, in 76 cases as a little over 14 per cent. The celebrated operation of Dr. Mott,[1] performed during 1828, for sarcoma of the left clavicle, which required nearly four hours for its performance, and in which forty ligatures were employed, was a case of partial excision, though from the size of the tumor and the part of the clavicle removed—the inner end—was really a more formidable operation than the majority of cases of complete excision. Dr. Mott referred to it as his "Waterloo operation," and said that it was without a precedent, and far surpassed in tediousness, difficulty, and danger anything he had ever witnessed or performed.

A CASE OF SEVERE TOXEMIA; RECOVERY AFTER TREATMENT WITH COLD BATHS.

By KNUT HOEGH, M.D.,
OF MINNEAPOLIS.

THE patient, Mrs. G., thirty-two years of age, entered St. Barnabas' Hospital on September 2, 1897. A diagnosis of multiocular cyst of the left ovary having been made, the usual preparatory treatment for operation, consisting of bathing, scrubbing, shaving, evacuation of the bowels, and restricted diet, was carried out according to routine practice. On the morning of the operation breakfast was not allowed. An enema was given, and at eight o'clock a hypodermic injection of ⅙-grain of sulphate of morphia was administered. At nine o'clock the patient was etherized and oophorectomy performed. The hands of the operator and assistants had previously been thoroughly scrubbed, the operating-gowns, caps, and dressing material sterilized in Schimmelbusch's steam sterilizer, the instruments boiled fifteen minutes in a ten-per-cent. solution of sal soda, and the silk suture material, an hour in a five-per-cent. solution of carbolic acid. Böckmann's catgut was also used.

The sterilization was accomplished under the personal supervision of the operator. The operation was as easy as an oophorectomy can be, and no mishap occurred, except that a knuckle of bowel, about four inches long, was twice forced out of the wound by the vomiting and retching of the patient, and was immediately replaced by the fingers covered with gauze wrung out of sterilized hot water. In puncturing the cyst, a very small quantity of its contents, of an apparently bland nature, escaped along the trocar. There was no bleeding and the emptying of the cyst largely occurred outside of the abdominal cavity. Nothing but the operator's hands was introduced into the cavity; sponging or flushing was not employed, and the peritoneum was not interfered with in any way. Including the insertion of sutures in separate layers and the application of the dressing, the operation occupied exactly thirty minutes, and at its completion a most hopeful outlook was presented.

Some hours after the operation five ounces of urine was withdrawn by catheter, and for the first few days the secretion of urine was normal. On the evening of the first day the temperature rose to 100.4° F. and the pulse to 84; the patient complained of abdominal pain; no flatus was passed; nothing but hot water was given by mouth and drugs were not administered. On the following day the morning temperature was 100.6° F., the evening, 100.8° F., and the pulse varied from 90 to 98. The patient complained of severe abdominal pain and slept but little. The urine was withdrawn by catheter, and while scanty was as much as could be expected considering the small quantity of hot water taken. Food was not given during the thirty hours following the operation. At the end of this time a small quantity of broth and a little dry toast was allowed. Nothing more was given that day, as nausea was provoked. The patient passed a restless night, having short snatches of sleep interrupted by pain in the back. Forty-six hours after the operation she vomited a dark-green fluid. The temperature remained very much the same as on the previous day—100° F. to 100.8° F., and the pulse, 88 to 92. During the day she repeatedly vomited a little dark-green fluid. She rested but little during the night, and the next morning vomited a somewhat larger quantity of similar appearance.

Sixty-six hours after the operation the temperature was 99.9° F., the pulse had risen a little, and the patient had a somewhat collapsed appearance. She had urinated spontaneously, but neither fecal matter nor flatus had passed. The wound looked healthy, the abdomen was slightly distended, but no ascitic fluid could be discovered. Hourly doses of ¼-grain of calomel were administered, but the vomiting continued and no signs of intestinal peristalsis appeared. On the afternoon of the fourth day, eighty hours after the operation, the temperature began to rise; at 4 P.M. it was 102.6° F., pulse, 112; at 8.45 it was 103.2° F. and the pulse, 118; the vomiting continued. The administration of two enemas of salines and turpentine resulted in a fairly large movement of the bowels. The vomiting, however, continued during the night and the next morning; it must have been feculent, as it was described as offensive, although still green. The patient appeared slightly delirious. The matter next vomited was brown in color. The calomel was continued and small doses of strained barley-water were given. The following morning, at the end of the fourth day, the stomach was emptied by means of a flexible tube, a large quantity of distinctly fecal matter being evacuated. The calomel was then stopped and citrate of magnesia given. The patient was very feeble and decidedly delirious, but answered questions rationally.

During the forenoon of the fifth day the temperature remained 102.6° F., while the pulse increased in frequency and lost in volume and strength. An enema at noon produced a loose dark-brown evacuation. As the vomiting con-

[1] *American Journal of the Medical Sciences*, January, 1883.

tinued it was deemed advisable to use the stomach tube again, and about a quart of yellowish-brown fluid of fecal odor was removed. She was more delirious and restless than before, the pupils were dilated, the lips dusky, and a clammy perspiration covered the upper part of the body; temperature, 103.6° F., pulse, 148. It seemed as if the end were approaching, an event the more deplorable as the operation had appeared one of unusual simplicity and freedom from complications. As a last resort, she was carefully lifted from her bed and placed in a portable bath-tub filled with water at a temperature of 90° F. A towel rung out of ice water was placed upon her head, and the temperature of the bath reduced to 70° F. by adding ice to the water. She was kept in the bath ten minutes, during which time the body and limbs were briskly rubbed. She enjoyed the bath very much, spoke intelligently on being taken out, and went to sleep immediately after. An hour and a half later the temperature was 100.3° F., while the pulse still remained 148. A hypodermic injection of $^1/_{30}$ of a grain of strychnia was administered.

A little less than three hours after the first, a second bath was given, the temperature of which was lowered to 75° F. After this bath the patient's temperature was 102° F., pulse, 134, and a slight amount of flatus was passed, which was observed both by the patient, who had become more rational, and by the nurse. After a short time she became restless and vomited again, whereupon the stomach tube was used, and another hypodermic of strychnia given. At midnight, another tub bath reduced the temperature to 101.8° F., after which the patient became more quiet, and the pulse, which had remained 138, became perceptibly stronger. As she had not passed any urine since seven o'clock the previous morning, the catheter was used, and an ounce and a half withdrawn.

At two o'clock on the morning of the fifth day, that is before the one hundred and twentieth hour was completed, a fourth tub bath was given which calmed the restlessness and brought down the temperature to 100.8° F. and the pulse to 128. At four o'clock another hypodermic of strychnia was given, and at five, she was given a fifth bath which had the usual quieting effect. The temperature was then 100° F. in the rectum, and the pulse 124. The stomach was again emptied by means of the tube. At six o'clock hot water and whiskey, three ounces of each, were given per rectum, whereupon she went into a somewhat restless sleep. During the forenoon of this, the fifth day, two more tub baths were given and the stomach again emptied. The fluid removed was now green and did not smell so badly. In the afternoon, another tub bath was given, although the temperature had not risen above 100.6° F., but the patient wanted it, and, as it seemed to have a good effect upon the pulse which had dropped to 120 and finally to 110, it was deemed advisable. She was then given some barley-water which was retained an hour or more. At eleven o'clock at night the stomach was again washed out, and for the first time the contents were not feculent; there had been a slight natural movement a short time previously. The catheter had been used several times during the day, and altogether about seven ounces of urine obtained.

From the morning of the sixth day there was a steady improvement. The pulse went down to 104, occasionally rising to 110, the temperature ranged between 98° F. and 99.6° F., and there was a corresponding improvement in the general condition which continued until recovery was complete. It would be tedious to dwell upon the successive steps of her convalescence; it is only necessary to mention that she received in all ten tub baths and that the stomach tube was not used after the end of the seventh day. Her recovery was slow owing to extreme weakness, and was complicated by the appearance of a number of carbuncles on the back, which were satisfactorily treated by parenchymatous injections of a six-percent. solution of carbolic acid and applications of permanent wet antiseptic dressings. October 10th she returned to her home perfectly well.

In trying to account for the condition which came so near being fatal (and at one time was hourly expected to be so) it seems reasonable to assume that it was due to an absorption of toxins. The case did not impress the physicians as one of septic peritonitis, for there was no fluid or other effusion or exudation discoverable in the abdominal cavity, nor was there marked tympanites, at least not enough to correspond to the gravity of the constitutional symptoms, nor was there pronounced abdominal tenderness. At the end of the sixth day, when the crisis was over, the abdomen was absolutely flat and entirely free from pain upon pressure. It seems to me that the best explanation of the condition is the assumption of absorption through the edematous mucous membrane of toxic products from the paralyzed intestinal tract.

Why was the intestinal tract paralyzed? Could it have been the result of the administration of morphia before the operation? Was it due to the ether narcosis or to the compression of the knuckle of bowel by the rather violent vomiting and retching during the operation? Is it possible that the escape of, at the very utmost, two teaspoonfuls of the apparently bland cyst contents could have produced it? And if so, should we not rather have expected peritonitis, and not this paretic condition of the intestinal tract?

The patient was of large frame, looked strong and robust, and had always been healthy; but her mother and a brother are said to have died after surgical operations. Does this point to the possibility of a congenital lack of resistance and power of reaction? Is such a paralysis of the intestinal tract to be classed with the anuria which sometimes follows abdominal operations, to be looked upon as an effect or evidence of shock?

It seems to me, and it appeared so to other physicians who saw the patient, that she would not have survived but for the cold baths. It is certain that they were very grateful to her at the time, although after her recovery she could not remember the first ones. That they were beneficial was evidenced by the lowering of the temperature, the strengthening of the heart's action, and the mental clearness which followed their administration. I was led to use them in this case because of the good effect which usually accompanies their employment in typhoid fever when the toxin poisoning is often the main cause of a fatal issue.

AN ADDRESS.

SANITARY SCIENCE, THE MEDICAL PROFESSION, AND THE PUBLIC.[1]

BY HERMANN M. BIGGS, M.D.,
OF NEW YORK;
PROFESSOR OF THERAPEUTICS AND CLINICAL MEDICINE AND ADJUNCT PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE; PATHOLOGIST AND DIRECTOR OF THE BACTERIOLOGICAL LABORATORY OF THE NEW YORK CITY HEALTH DEPARTMENT.

IN an address on public medicine delivered before the British Medical Association some years ago, Sir Charles Cameron referred to a writer in the *Scotsman* who objected to the appointment of medical men engaged in practice as officers of health, on the ground that "no sane body of men can bring themselves to believe that medical practitioners, whose livelihood depends upon sickness, are likely to exert themselves in exterminating it." Dr. Holmes once humorously said, "Physicians desire for their patients great longevity with frequent illness." To such an audience as this arguments or proofs are not necessary to refute these suggestions.

The history of sanitary science is indissolubly related to the history of medicine, and its achievements may almost be written in the recital of the work, investigations, and discoveries of medical men. It may perhaps be justly said, that no class or profession has contributed as much as the medical profession to the advance of civilization, to the prosperity of nations, and to the preservation and prolongation of human life, all of which are closely related to the vast contributions to the progress of civilization which have been made by sanitary science. Sanitary science aims to prevent disease. In former times at least four-fifths of all deaths were due to preventable causes, and even now, when the death-rate has been reduced to a quarter of what it once was, still one-third of the deaths occurring in our large cities are due to distinctly preventable diseases.

During a discussion in the British Parliament of a bill for the protection of the public health, one of the greatest English ministers, Disraeli, pronounced these memorable words, "The public health is the foundation on which repose the happiness of the people and the power of a country. The care of the public health is the first duty of a statesman." England has long and justly been regarded as the birth-place and home of sanitary science. English methods in sanitation have been the models for the world. No other country has had in modern times so high a standard of public health and such low death-rates. These conditions have, without doubt, largely contributed in placing the British nation foremost in civilization, and have assisted much in laying the foundation of, and in building up, the British empire, in which is included to-day nearly one-quarter of the world's population. Such results are, in fact, the logical and far-reaching consequences of broad statesmanship in sanitary matters.

[1] The anniversary discourse delivered before the New York Academy of Medicine, October 21, 1897.

So complex are the relations, that it is impossible, even after the most careful consideration, to gain an adequate conception of the vast influence which the health of a nation has upon its material prosperity and its standard of morality. We realize more fully how close is the relation of the public health to the material prosperity of a community, when we recall the deadening influence on business and commerce produced in 1892 by the appearance in New York harbor of several ships, each with a few cases of Asiatic cholera on board, and the occurrence of a dozen cases in New York City itself. Almost a panic was created among the more fearful of the inhabitants. All the Southern, Central, South American and Mediterranean ports were quarantined against New York, and but for the short duration of the outbreak a most serious interference with commerce would have resulted.

The appearance at that time of cholera in Europe and in New York was the result of sanitary neglect. We realize how dearly this was paid for, when it is remembered what the epidemic of cholera in 1892 cost the city of Hamburg. Can one by any stretch of the imagination conceive of the terrible results which would follow the extension of such an epidemic to a number of the large cities of Europe and the United States, or over the whole continent of Europe, as occurred in the great epidemics of earlier times? Consider the results which only this year followed the introduction, at the end of the season too, of yellow fever into some of the Southern cities. The material loss has been enormous, although the actual number of deaths comparatively insignificant. The expenditure, on sanitary and quarantine improvements, of one-tenth of the loss involved in this insignificant epidemic would render another introduction of yellow fever well-nigh impossible. With the numerous close and rapid lines of communication which now exist between all parts of the civilized world, the rapidity of extension of one of the medieval epidemics would be frightful to contemplate, should sanitary conditions and lack of sanitary knowledge rendered such an epidemic possible. In temperate climates we have no longer reason to fear the occurrence of epidemics of any diseases more terrifying than scarlet fever, measles, typhoid fever, and diphtheria, and the occurrence of an epidemic of any one of these is to be chargeable to remediable sanitary defects.

The public health bears quite as close a relation to public morality as to general material prosperity. Sickness brings in its trail, especially among the poor, uncleanliness, poverty, misery, wretchedness, destitution, and death. The physical and the moral man are interdependent. That which degrades one, degrades the other; individual exceptions to the rule do not invalidate its force.

The most casual review of history shows in a striking manner the extraordinary improvement which has taken place in the public health in modern times. The plague and the other great epidemic diseases of the Middle Ages, which decimated and sometimes well-nigh exterminated the human race, are vanquished; smallpox, typhus fever, epidemic dysentery, and cholera have been restricted to the narrowest limits. The prevalence, in temperate climates and under favorable sanitary conditions, of yellow

and typhoid fever has been diminished to a small fraction of what it formerly was. Diphtheria and hydrophobia are now absolutely preventable, and even the less alarming, because more familiar, but hardly less fatal diseases, measles, scarlet fever, whooping-cough, and summer diarrhea—a formidable array of preventable affections—have been confined by the energies of the sanitary authorities within much narrower boundaries. The great plague of modern civilization, tuberculosis, shows a steady and continuous decline in its death-rate, and the most gratifying improvement in the percentage of recoveries from it, as the result of improved general and personal hygiene. Smallpox, in former times with all its terrors, before the discovery of vaccination, was scarcely more to be dreaded than tuberculosis is even now. Smallpox then caused a relatively smaller proportion of deaths than tuberculosis does to-day. We are all familiar with pulmonary tuberculosis. It is seen everywhere; it occurs among all classes of the population. It is insidious, and extends slowly; it is not dramatic in the manner of its appearance or course. As it is so familiar to everyone, we do not fear it. We neglect it; and many would deny proper sanitary supervision and refuse to provide special hospitals for the care of the poor suffering from it. Therefore, its ravages still continue, and it causes nearly one-seventh of all deaths, and nearly one-fourth of all deaths among the adult population, although, be it remembered, no disease is better understood or more preventable; none more amenable to simple and easily applied measures of cleanliness and disinfection. A consumptive may be absolutely free from danger to his immediate family and to his most intimate associates, provided only simple precautions be observed.

But at last we may hope that light is breaking upon sanitary authorities, the medical profession, and the people. Rational measures of prevention are taking the place of insane fear, or helpless, hopeless, ignorance and neglect, and before another generation has passed away the death-rate from tuberculosis in cities under the best sanitary control will, I believe, be less than one-third what it is in New York to-day. I do not wish this statement to be received as the opinion of an enthusiast; but as the deliberate conviction, reached after most careful and prolonged consideration and study, of one who has had considerable experience in sanitary matters and exceptional opportunities for the investigation of this dread disease.

The diminution in the number of deaths occurring from all causes in proportion to the population is shown in the most striking way when we compare the present with previous conditions. The healthfulness of a community or locality is to be judged by the statistics of the number of cases of sickness and death considered in relation to their causes. The condition of the public health should be studied, not simply with relation to the number of deaths or number of cases of sickness in proportion to the population, but also with relation to the nature and preventability of the diseases which cause the morbility and mortality. The mortality is usually expressed by stating how many persons die each year to each thousand of the population. In the Seventeenth and Eighteenth Centuries the average annual death-rate per thousand living, throughout the civilized world, probably varied from 50 to 80, that is, of every thousand persons in the population 50 to 80 died each year. The average duration of life of each person born was not more than fifteen to eighteen years. From 1628 to 1635, in London—these years being free from pestilence—the average death-rate was 50 per thousand, and the absolute annual mortality for twenty-four years, from 1620 to 1643, inclusive, was nearly 80 per thousand. With what incredulity would the prediction have been received two hundred years ago that the then average annual death-rate of 80 per thousand in England would be reduced at the present time to 17. The mortality during 1894 in London was only 17 and a fraction, or less than one-quarter of that of two hundred years ago. The mean expectation of life at birth one hundred years ago in London was only about nineteen years, the annual death-rate being 51 or 52 per thousand. At the end of the first half of this century it had already diminished more than one-third, to an estimated 30 or 35 per thousand, and as the century draws to an end it has diminished again to only 17 or 18, and the average duration of life has increased to more than 40 years, or more than doubled during the century. From 1770 to 1780 smallpox alone caused a higher annual death-rate in London than diphtheria, croup, consumption and all other tuberculous diseases, measles, smallpox, scarlet fever, and typhoid fever together caused in New York last year. Fever at the same time caused an even greater death-rate, and in the Sixteenth-Century plague, cholera and dysentery, diseases which are now practically extinct, annually destroyed nearly twice as many of each thousand of the population as now die from all causes added together. More than 40,000 people died in Paris during one epidemic of smallpox in the last century, and a third of the population of Iceland in another. Ten per cent. of the population of a city or country were often destroyed during one epidemic.

It is perhaps desirable to define more specifically what is meant by infectious, contagious, and communicable disease. Infectious diseases are those caused by some simple form of animal or plant life, which possesses, under favorable conditions, unlimited powers of reproduction. The contagious diseases include those infectious diseases which are transmitted by contact or proximity to the infected individual or infected material. For convenience we refer to another class of the infectious diseases as communicable, in distinction from the contagious, because the susceptibility is far less general and the means by which they are transmitted are well understood.

In the communicable diseases the observation of simple measures of prevention almost entirely robs them of danger to others. This is not true of the contagious class, which includes smallpox, scarlet fever, measles, chickenpox, whooping-cough, and typhus fever. The communicable diseases include diphtheria, typhoid fever, tuberculosis, cholera, and some others of less importance, in all of which it is possible to reduce to a minimum the danger of transmission by the observation of simple measures. In diphtheria the germs causing the disease are contained solely in the discharges from the nose and mouth; in typhoid fever and cholera they are contained

only in the discharges from the stomach or intestines; in pulmonary tuberculosis, or consumption, only in the expectorations. It at once becomes evident that very different measures of prevention are to be adopted in these different diseases. In the contagious class, it should be said, we are as yet unable to adopt any measures which will protect an exposed and susceptible individual.

The most serious array of preventable diseases with which we have at present to contend are those which are highly contagious, such as measles, scarlet fever, and whooping-cough, and a group of infectious diseases, partly communicable, such as diphtheria, typhoid fever, summer diarrhea, pneumonia, influenza, and some other affections of the respiratory tract. In all the diseases of this list there has been a constant decrease in frequency of occurrence, excepting diphtheria, pneumonia, and the epidemics of influenza. Diphtheria has been gradually increasing for a number of years in all of the larger cities until the discovery of the diphtheria antitoxin in 1894. With the extensive use of this remedy it commenced to diminish rapidly, and in Berlin and Paris the death-rate from this disease has been reduced to almost one-quarter of what it previously was. Much has also been accomplished in New York, a diminution of forty per cent. having taken place; but as yet the field is by no means exhausted. The constant increase of diphtheria in the large towns was a remarkable and inexplicable fact, until the observations first made on a large scale by the New York City Health Department showed how it was disseminated through the diphtheria bacilli present in the throat during convalescence and in health.

In the control of whooping-cough, measles, and scarlet fever, exceptional difficulties must be contended with, especially in the great tenement-house population of New York. These diseases possess many features in common. In no one of them is the cause known, and, therefore, the difficulties in their control are greatly increased. These difficulties arise in part from the great crowding in our tenement-house districts, and in part from the fact that they are regarded by the ignorant as only children's diseases, and consequently inevitable. They are, therefore, neglected, and, as a result, being excessively contagious, are prevalent and familiar, and unnecessarily destroy many hundred lives in this city every year—more than ten times as many as smallpox and cholera together; yet there is more dread of the latter two diseases than of all other zymotics combined.

I believe that much could be done to reduce the death-rate from the diseases under consideration if they were managed in an efficient and intelligent manner and with a genuine determination to restrict and prevent them. Probably a satisfactory result will only be attained by the education of the masses, so that they will be able to estimate the actual danger attending these diseases. This opinion as to the possibility of their prevention is justified, as has been shown by Dr. Hill, Medical Officer of Health to Birmingham, by the success which has attended the measures taken in that city with regard to scarlet fever. In Birmingham the annual average death-rate during three periods—1875 to 1878, 1878 to 1882, and 1883 to 1889—has been reduced from 425 per 100,000 to 235 and to 72 during the last period, the number of deaths being only about one-sixth as many as during the first. This reduction has been ascribed to the compulsory reporting of cases and to the hospital accommodations which have been provided for the care of patients with this disease. During 1875 only 20 cases of scarlet fever were admitted to the hospital. In 1889 this number increased to 3759. During the intervening period the decrease in the prevalence of the disease was coincident with the knowledge obtained of the occurrence of cases, and the extent to which the public availed themselves of the advantages of hospital care.

It is said by Dr. Hill that "the prejudice against hospital treatment, which was general at first, has mostly disappeared, and the public now appreciates the advantages to health and life of an institution which enables patients to be removed from unhealthy rooms and other unfavorable conditions to a properly equipped hospital, where better air, suitable food, superior medical treatment, careful nursing, and all those appliances are at hand which a hospital affords, but which are wanting in the homes of the poor." The mortality of the disease in the hospitals varies from five to six per cent. It is noted also that "the social and professional objections to the act controlling the notification of infectious diseases have been proved to have had no foundations whatever. The distrust and friction between the practitioner and the medical officer of health, which were predicted, have not appeared, the concealment of disease which was to have followed has not occurred; the sacred confidence between patient and doctor, which was to have been destroyed with most disastrous results, remains inviolate. And so every theoretic objection which timidity, selfishness, or ignorance could find or invent has been refuted by practical experience.

"One of the objections put forward in this matter, and which deserves special comment, was that notification would be useless in the absence of isolation-hospitals. Without seeking to refute this assertion, which, however, would not be difficult, it may be said that to make compulsory the notification to the sanitary authorities of cases of infectious disease which ought to be isolated constitutes one of the strongest inducements to provide hospitals for their care. These follow as a natural sequence. Every town should provide at least one bed in such a hospital to every thousand of its population.

"The past triumphs of preventive medicine have been achieved in relation to the majority of the scourges afflicting mankind through cleanliness. Malarial fever, smallpox, and hydrophobia have yielded to different and special influences, but the plague and the medieval epidemics have been banished by cleanliness. Typhus and cholera, which formerly wrought such terrible havoc where filthy conditions prevailed, have disappeared through the influence of cleanliness. Typhoid fever is becoming less common through the improved cleanliness and better water-supply of our cities; and while filthy conditions do not seem to give rise to measles, whooping-cough, scarlet fever, and diphtheria, yet there can be no doubt that they

seriously aggravate their severity. Nevertheless, the old lesson of thousands of years ago is still unlearned. The sanitarian must still go forth and try to teach that without cleanliness health is impossible."

A Royal Commission, appointed to inquire into the sanitary condition of the British army in India in 1859, found that during a long period the annual average death-rate had remained 69 per thousand. The inquiry resulted in extensive improvements in the housing, clothing, food, and occupation of the soldiers. After these were carried into effect there was a steady decline in the death-rate, the rates for 1886, '87, and '88 vary between 14 and 15.2 per thousand, or less than one-fourth of that previously prevailing; in some years the rate has been even lower.

The impetus to modern sanitary progress may be said to have commenced in England with the passage of the Public Health Act of 1875. Since that time there has been a diminution of twenty per cent. in the death-rate for the whole of England and Wales, while in certain individual communities the fall has equaled thirty per cent., and in Maidstone the unusual figure of forty per cent. has been reached. In New York City, in more recent years, an equally great reduction in the death-rate has been obtained in a shorter period. The average annual death-rate for the ten years ending in 1893 was about 26 per thousand of the population, while the present year will show a death-rate of only 19 and a fraction—a reduction equaling about twenty-five per cent. since 1893. The improvement in New York is especially notable, because it has not been the result of, or associated with, any single great public work or improvement, such as the introduction of a purer water-supply or a better system of sewerage, but is the result of a gradual improvement in every respect in the general sanitary conditions—the improvement in the character of the housing of the poor, the condemnation of rear tenements, the prevention of overcrowding and the habitation of basements and cellars; the improvement in the character of the pavements, and in the cleaning of the streets; the improved character of the water-supply, through a better control of the watershed; a closer supervision of foods, attained by a rigid inspection of meat, fish, and fruit, and the precise control of the milk-supply; the inspection and supervision of offensive trades; the application of modern scientific discoveries in the supervision and control of infectious diseases, and the education of the people in all matters connected with general and personal hygiene.

While the splendid results which have been obtained may well serve for congratulation, it is not to be supposed for a moment that the limit of the improvement has been reached, or that the resources of preventive medicine have been exhausted. On the contrary, the reverse is true, and while we cannot rationally hope for as rapid a reduction of the death-rate in the future as has been the case in the past, because the limit placed by the natural duration of human life is being more nearly reached with each advance, yet it may be said that almost as much remains to be done as has been accomplished in the immediate past. Notwithstanding the increased strain which is associated with the complexity of modern civilized life, there is no inherent reason why the death-rate, even in such a densely populated city as New York, should not be reduced to 14 or 15 per thousand, or even less, and the average duration of human life increased to fifty years or more.

In speaking of sanitary authorities in relation to the medical profession I desire to refer more especially to the Board of Health of New York City and its relation to those who practice medicine it this city. I would not be understood as speaking for the Health Department, but wish to give only my personal impressions as one of its officials.

The attitude of the Board of Health of New York City toward the medical profession has been in many respects more advanced than that of any other sanitary body in the world. The broad position has been taken that it is the function of the Health Department to furnish to physicians all such specific and general information and assistance in relation to the infectious diseases as can be afforded by thoroughly equipped bacteriologic laboratories, in which the work is fully abreast of the most recent observations in scientific medicine. The sanitary authorities of New York City were the first in the world to assume this position, and while their example has been widely followed in the great cities of this country and Greater Britain, yet nowhere else has this position been frankly taken and consistently followed to the extent that it has been here. It has been the attempt of the Health Board to introduce new measures or to adapt existing measures to the new requirements of every additional observation with regard to any of the infectious diseases which had a practical bearing on prophylaxis or therapeutics. Two considerations, as I interpret the action of the Department, have mainly influenced the Board in the adoption of this position: (1) The desire to extend as rapidly as possible the knowledge of the most recent discoveries in regard to the infectious diseases and the means for their restriction, prevention, and cure. (2) The desire to afford the general practitioner of medicine, without charge, such expert assistance and special information as may be useful to him in clinical work, which could not be otherwise obtained, excepting at greatly increased trouble and considerable expense.

It has been the hope of the Board of Health that such a course would materially aid in establishing more cordial and mutually confidential relations between the members of the medical profession of this city and the Health Department, and thus facilitate the work of the Department; and it was thought that the information thus offered would be, in a sense, received in lieu of the money compensation given to private physicians in some countries for reports of births, deaths, and cases of contagious disease. In this country no such compensation is offered; the position assumed being that it is the duty of the physician to make such reports, and that no payment should be received for the discharge of such a duty. Whether this attitude is a proper one or not does not concern us now. My own belief is that the welfare of the community and the rights of the medical profession would be better conserved by the payment of money for reports of the

occurrence of births, deaths, marriages, and contagious diseases.

In considering the relations of the sanitary authorities to the medical profession the fact must be kept in mind that the points of view of the Health Department and of the profession are widely separated. The interests of the community, as guarded by the sanitary authorities, and of the individual practitioner of medicine, are apparently divergent, but the real interests of the practitioner, who is at the same time a citizen, are quite in line with those of the community, and it cannot be for one moment assumed that the conscientious, intelligent, and broad-minded physician will view the situation from any point other than that of the community as a whole. Whether the practising physician then arrives at the same conclusion as the Health Board as to the proper course to be pursued by the sanitary authorities will be a question of opinion; there will be harmony of purpose, and, at most, only a difference of opinion as to the methods to be adopted to secure a common object. Considering the apparently diverging interests of the physician and the community, it is not strange that the action of the Health Board and the position adopted by it in relation to some of the infectious diseases should be the subject of criticism by members of the profession.

But physicians apparently often think that radical measures are adopted by the Board of Health after too little consideration and without a full knowledge of all the facts bearing upon the situation—a much fuller knowledge than, from the nature of the conditions, the members of the medical profession can possibly possess. Consequently, the Health Department is severely and often very unjustly criticised for a course which is the only logical one, and one wholly justified when all of the facts are taken into consideration. The medical profession sometimes forgets that the Health Board legislates and acts for the whole city, not for special sections or for individuals; that many measures which are not demanded or necessary in the best portions of the city are required for the well-being of the inhabitants of the tenement-house districts, and also that special legislation is generally objectionable, must be very carefully restricted, and only resorted to when it has an absolutely special application.

Great discretion has always been exercised in enforcing sanitary measures and the provisions of the Sanitary Code in New York City, and much greater liberty is allowed in private houses than in tenement-houses, because of the lessened danger to the public as a whole. It has never been the policy of the Health Department to interfere in any way in the management of cases of contagious disease occurring in private houses as long as there is no exposure of persons outside of the patient's family. The Department requires that such precautions shall be taken as will protect persons outside from possible infection, but in the family the Department does not interfere. This has always been the policy and the course pursued; but it does not seem to have been fully understood by many of the members of the medical profession.

Physicians occasionally criticise the Health Department for indiscretion or want of judgment on the part of its employees. These criticisms are often justifiable, but unfortunately, they are not, as a rule, made directly to the Health Board, so that the facts may be determined and any wrongs or defects remedied; often they are facts made known through the medical journals or through discussions in the medical societies, and thus, only long after the occurrence the Board becomes aware, indirectly, of the cause of the complaint. There are over two hundred physicians in the employ of the Department, all appointed after passing a civil-service examination. Their instructions are always definite, specific, and detailed as regards duties, and all employees of the department are strictly held to account for their actions. Judgment and discretion cannot be furnished to its employees by the Health Board, or by any other body. Every possible precaution is taken to prevent any just cause for complaint, and each and every one is most carefully investigated, and, so far as is possible, the cause removed and the errors corrected. The Board, however, cannot remedy defects which are not brought to its knowledge. Investigation has also shown in many cases in which complaints have been directly made to the Board that the physicians have been misled by the statements of the patient or family, or by lack of knowledge of all of the facts in the case. The greatest cause for misunderstanding and complaint arises from the fact that only with rare exceptions can physicians be induced to read the circulars of information issued by the Department in regard to its work and the methods pursued. Most of the unsatisfactory results in the work of the bacteriologic laboratories are due to the failure on the part of physicians to follow specifically the directions given. It is impossible where examinations are made from several hundred cases each day, as frequently occurs, to attain anything like a reliable service unless the specific and definite directions given are accurately followed. Still, I think it may be fairly said, that as a whole the work of the Health Department of New York City during recent years has deserved and received the commendation of the large majority of the medical profession of this city.

The duties and reponsibilities of the sanitary authorities with relation to the general public are numerous and comprehensive. To a very great extent the general welfare of the community is in their hands. Everything which is detrimental to health or dangerous to life, most broadly interpreted, is properly regarded as coming within their province, and so wide should be the construction of the law that everything which improperly or unnecessarily interferes with the comfort or enjoyment of life, as well as those things which are detrimental to health or dangerous to life, should become the subject of consideration and action. Sanitary authorities must protect the community from the individual, "the greatest good to the greatest number" furnishing the first rule of action. They must ensure the safety of the community as a whole, and, so far as possible, of each person in it, by protection of the community from its component parts, and then again from each other. The interests of the individual and of the community are often divergent, or apparently divergent; for example, in factories and noxious trades, the observa-

tion of such sanitary precautions as are necessary for the protection of the health of employees often involves serious expenditures which fall upon the owners. Again, the welfare of the individual frequently requires such changes in the physical condition of property—tenement-houses for example—as the tenants would not themselves demand. In cases of contagious disease it may sometimes be to the interest of the individual to be left in his own home, while the good of the community urgently requires his removal to an isolation hospital. It becomes at once evident, in all such instances and many similar ones, that it is the plain duty of the sanitary authorities to exercise judiciously, but firmly, the autocratic powers given to them by law. They should not interfere in regulating individual action, at least only to a very limited degree, unless such action involves danger or detriment to the community.

A glance at the functions performed by sanitary authorities shows how broad is their scope: Primarily, sanitary science aims to insure to a community and to each individual an abundant and pure supply of air, light, water, and wholesome food. In the great aggregations of population found in our large cities the preservation of the purity of the air and insurance of an abundance of light and good ventilation involves most comprehensive measures relating to the character of the habitations—their cleanliness and the cleanliness of their surroundings, including the streets; the provision of efficient plumbing; good sewerage; sufficient air-space to the individual, that is, the prevention of overcrowding; protection against noxious vapors or odors arising from offensive trades, slaughter-houses, gas-houses, decomposing animal and vegetable matter, and the purity of the atmosphere, so far as suspended solid particles are concerned.

These functions of the sanitary authorities are performed through official inspections made by inspectors of plumbing, ventilation, overcrowding, nuisances, noxious trades, and by the general sanitary inspectors. An abundant and pure water-supply is one of the first and most essential factors in insuring healthfulness in a large community. Without this, cleanliness, in a broad sense, is impossible; and, of course, cleanliness is the first consideration in all sanitary work. Further, the purity of the water-supply is a most important factor in the prevention of many forms of water-borne disease. New York City is particularly fortunate in this respect; no great city of the world has a more abundant or purer water-supply. In this connection we must not confuse what is unpalatable to the taste or appearance with actual purity. At certain seasons of the year the Croton water is unattractive in appearance and has a disagreeable odor and taste, due to suspended vegetable matter. There is no evidence, however, to show that this is really detrimental to health.

It is also incumbent upon the sanitary authorities to prevent adulteration and to guarantee the wholesome quality of food. This is attained through specially trained inspectors of meat, milk, fish, fruit, and general foods. The purity and quality of various drinks must be inquired into, and the relative food values of different articles of diet determined. Not only must an abundant supply of light, pure air, and water be insured in the homes of the individuals of the community, but the same must be found where they are engaged in their daily occupation, in factories, mercantile establishments, etc.; all the sanitary conditions surrounding these must be supervised.

The general sanitary inspections include inspections relating to street excavations, wells, privies, stables, the conditions surrounding the removal of garbage and dead animals; conditions in public places and places of assembly; the manner and place of burial, etc.

A special feature of the work relates to the restriction and prevention of infectious diseases. Personal and general cleanliness is to be regarded as a most important and almost universally valuable safeguard against all forms of infection, yet the most ingeniously devised systems of plumbing, drainage, and street-cleaning cannot avail to protect the individual from direct contagion. The greatest value of the system of notification of the existence of contagious disease is due to the fact that it enables the authorities to adopt intelligent and scientific measures to prevent the direct transmission of contagion. Their energies are not then wasted in ill-conceived and inefficient measures. It should be clearly understood that the reporting of the occurrence of infectious diseases is most useful only when the direct causes of the diseases reported and the methods of their transmission are accurately known and amenable to control. The public, and even the medical profession, have not yet fully learned the lesson, though it seems almost axiomatic, that different diseases require to be controlled by different methods, and the more accurate and extensive our knowledge of the nature and causes of the different infectious diseases the more unlike become the intelligent measures devised for their prevention.

The condition of the general sanitary administration in this country now much resembles that existing in Great Britain twenty-five years ago, previous to the enactment of the Public Health Act of 1872. There is everywhere lacking the presence of intelligent, thoroughly trained sanitary officers, because there are no provisions in this country for the education of men in matters of public health. The knowledge required for the intelligent discharge of the duties of medical officers of health is broad, comprehensive, and entirely unlike that required for a medical adviser. There is, so far as I am aware, no place in this country where the complete training required can be obtained. Consequently, outside of the large cities the medical officers are generally physicians without special knowledge, experience, or ability in the performance of the work required. Unfortunately, too, the compensation is insufficient and the tenure of office insecure, frequently depending upon local political influences. It, therefore, becomes almost impossible that such officers should act in the prompt, firm, and fearless manner often required, and especially is this true when the interests of persons prominent in the community are jeopardized by their action. The community, in other words, must suffer because the interests of its prominent members are different from those of the people at

large. In regard to even the larger towns and cities all this may be said with almost equal force.

There are no men to be found anywhere in this country with a broad knowledge of public medicine. In the great cities there are officers in the service of the health departments who, from practical experience and long training, have acquired the special knowledge requisite for the efficient discharge of duties in a narrow sphere of work. But even in the large cities none are to be found whose knowledge covers the whole sphere of public medicine. The great sanitary need of the time is for the establishment of training-schools in public health (similar to those existing in Great Britain), the education of physicians in the special knowledge required, and the enactment in the various States of laws requiring that medical officers of health should have diplomas in public health, such diplomas representing the requisite sanitary knowledge; and those not possessing such credentials should not be eligible for public-health appointments. The compensation for sanitary work should be larger, the tenure of office more secure, and the appointments made by State or National authorities, rather than dependent upon local influences.

As the country grows older and more densely populated, the cities larger and more crowded, the demand for intelligence in the administration of sanitary affairs will become more urgent. In addition to the improvement in local conditions, there should be added a National supervision exercised through a properly constituted National Bureau or Department of Health. With the fulfilment of these two requirements in the future, we may hope finally to attain more nearly ideal sanitary conditions throughout the whole land.

MEDICAL PROGRESS.

A Case of Tetanus.—J. RUDIS-JICINSKY (*N. Y. Med. Jour.*, Nov. 13, 1897) describes a case of tetanus following a bite in the thigh produced by a boar. Five hours later there had already developed stiffness of the muscles of the neck and jaws and tonic spasms of the diaphragm. The temperature in the axilla was 99° F. The wound was thoroughly curetted and irrigated with a strong solution of potassium permanganate, followed by hydrozone, and was then dressed with iodoform gauze and equal parts of iodoform and calomel. Forty grains of bromid of potassium and large doses of morphin were given every two hours, while chloroform was administered during the spasms. Twenty-four hours later treatment with antitoxin was commenced, about 40 c.c. being given every day for five days. Up to the time of the first injection the spasms had recurred with unpleasant regularity. From that time on they became lighter, and the intervals between them longer. The patient recovered.

The Best Gauze for Drainage.—HALL (*Boston Med. and Surg. Jour.*, Nov. 18, 1897), who has been testing the capilliary power of different gauzes, finds that wicking or cordine has a decided advantage over ordinary gauze wicking as it contains in a small compass a maximum number of longitudinal threads. In ordinary gauze each transverse thread proves a little obstacle to the upward progress of fluids. "A study lamp," says the writer, "which burns a pint of oil during an evening may teach a lesson in drainage. In most lamp-wicks the threads all run as nearly longitudinally as is consistent with stability of the fabric. Steps have already been taken toward securing the manufacture of an absorbent tape on the principle of the selvage. Such a tape, it is hoped, will supplant the faulty gauze drain."

Omental Grafts.—JORDAN (*Lancet*, October 30, 1897) used omental grafts in sixteen cases of intestinal resection in dogs. In every case their application worked disadvantageously. In dogs killed a short time after operation the omental graft was found to be thickened and adherent to surrounding coils of intestines. Later, it was changed into a dense fibrous ring which either constricted the lumen of the bowel or, contracting longitudinally, produced a sharp angle in the intestine, or threw the mucous membrane into folds, or by extensive adhesions with other coils of intestines so matted them together as to make their separation difficult or even impossible. Such conditions, even if they are not followed by obstruction of the bowel, cause so much disability and pain, that the practice of covering intestinal sutures with omental grafts should never be resorted to.

A Case of Combined Intra- and Extra-uterine Pregnancy at Term.—ROYSTER (*Amer. Jour. Obstet.*, December, 1897) reports that a negress, aged thirty-four years, was delivered by a midwife of a healthy male child. Forty-eight hours afterward, inasmuch as the midwife felt in the abdomen another child which she was unable to deliver, she sent for a physician, who, by introducing his hand into the uterus, made out that a living fetus at term was ontside of this organ. He advised operation, which was refused. The fetus lived more than a week, and then movements ceased. One week later, as the woman's temperature had begun to rise and death seemed imminent, she consented to operation. Celiotomy was performed, and a female child weighing four and one-half pounds was successfully removed. The placenta with its membranes was attached to the anterior abdominal wall, and it would not have been necessary to open the peritoneal cavity in order to remove the whole. This was done, however, accidentally. The patient recovered. The history in this case reveals the fact that during the third month of pregnancy, while squatting down to pass urine, the patient had had a sharp pain in the right side which caused her to call for help. She fell, half-fainting, and was carried into the house and put to bed, but recovered within a few hours. There was no external loss of blood.

A Curved Hypodermic Needle.—LEGRAND (*Bull. Gen. de Therapeut.*, Nov. 8, 1897) suggests that the use of a long curved hypodermic needle will enable the operator to more perfectly anesthetize with cocain those surfaces of the body which are difficult of access, especially the anal region. Such a needle has been tried by several European surgeons with the greatest satisfaction.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,

RECENT TYPHOID-FEVER EPIDEMICS.

THE serious outbreak of typhoid fever at Paterson, N. J., and in its neighborhood, caused as it was by a tainted milk-supply requires no comment on that account, but it brings into glaring light a most astonishing lack of proper dairy and milk inspection here at our very doors. First, the dairyman's three sons were ill with what had been carelessly diagnosticated "remittent fever," but which in reality was typhoid, and were allowed to continue their work in the dairy for a month. Secondly, the dairy inspection has been so outrageously lax that a large dairy supplying Paterson, Arlington, Dover, Newark, Morristown, the Oranges, Jersey City, and New York, was allowed to draw its water for all purposes, washing the utensils, cans, etc., *from a small stream, taking its water through a pipe only twelve feet below the outlet of the drain-pipe from the dairyman's privy*. Thirdly, the criminal carelessness of the proprietor who used water which he must have known was in imminent danger of being infected at any moment. Fourthly, the entire absence of any law in New Jersey requiring physicians in the country districts to report cases of infectious and contagious disease. To point out these salient points ought to be sufficient to bring speedy reform. Comment is unnecessary.

Even typhoid epidemics have their humorous side. A large number of the typhoid cases in Paterson were traced to ice cream which had been prepared from milk from the above-mentioned dairy, and which had been eaten at a "pure-food show" inaugurated by the good denizens of the town to show what they could do in that line. They did it.

The second epidemic to which we desire to call attention is that at Maidstone, England, in which up to date there have been nearly 2000 cases. As is usual in large epidemics, this was spread by water, the lake from which the water was drawn for the larger part of the town having been infected, through a camp of hop pickers. The percentage of cases is based upon the population of the entire town, but if the number of inhabitants of the central district, which was not supplied with the contaminated water, was known, it would show that in the parts of the town where the infected Farleigh water was drunk the percentage of cases was very much higher. The curious thing in connection with this epidemic is the significant immunity enjoyed by that part of the town which contained 17,000 persons, or nearly one-third of the entire population, there having been in this district up to date but thirty-five cases. To be sure, this particular section of the city was not supplied with the Farleigh water, but there was probably not a single inhabitant of the central district who had not relatives, friends, or business connections living in one or more of the districts which did use the Farleigh water, and they must have consumed a great deal of it at one time or another in going about their daily avocations, and yet there were only thirty-five cases in this district, as opposed to 1073 in the districts immediately surrounding. It does, therefore, seem as if the inhabitants of this locality were for some reason or other less susceptible, and in the course of his investigation the *Lancet's* commissioner made a special study of this point, and found that the epidemic was not only limited to those districts supplied with the Farleigh water, but established the curious fact that the greater number of cases occurred in the *higher parts* of those districts which were higher than the rest of the town, and this was particularly the case at the commencement of the epidemic. The second characteristic fact

noted was that the epidemic did not coincide with the distribution of the Farleigh water-supply only, but also with the higher altitudes.

It seems curious that while it is generally considered more healthy to live on high ground, the reverse seems to have been proven in the epidemic under consideration. This fact, however, has been noted before, as in Paris, where much typhoid fever has been noticed in such high districts as Belleville, Montmartre, and Les Batignolles, while the low-lying quarters near the Seine were comparatively free from the disease. This fact was explained by the Paris authorities on the ground that the sewer air traveled upward and that a greater volume of sewer air forced itself into the mains draining into the upper extremities of the sewer, and this would also seem to explain the fact that the Maidstone epidemic was almost exclusively confined to the higher parts of the city.

The *Lancet's* commissioner, however, finds that the manner in which the sewers of Maidstone are built and laid does not confirm this theory, and he calls attention to the fact that the great majority of sewers in Maidstone are pipe, that is to say, very small sewers, whereas, in Paris, the sewers are usually very large with proportionately less water, and hence, the downward flow does not prevent an upward current of air, whereas, when the sewer is small and the pipe nearly full of water, there is sufficient friction caused by the downward rush of the water to attract the air of the sewer-gases. It, therefore, would follow the flow of the water, and go down instead of up. While this is true, it seems that in Maidstone the sewer-pipes, though small, are poorly flushed, and the discharge of sewage is irregular, and though the air would probably travel downward in the morning when the sewers are full, it would scarcely be the case at night when the pipes are empty. And hence there would unquestionably be a steady flow of sewer-gas drawn by the warm air upward and into the houses, more especially at night, in houses in the higher portion of the town. It is at night that sewer air, as we know, produces the most deadly results, for there is naturally less free ventilation and the power of resistance of the sleeper is probably not so great as that of the person awake. Add to these considerations the fact that the domestic drainage of Maidstone is in anything but a good condition and that there are many closets without any flushing apparatus, and there are produced the favorable circumstances which weakened the resistance to typhoid infection when introduced by the medium of the contaminated water-supply in those who lived in houses in the higher parts of the city.

It also appears from the work of the commissioner that the sewers of Maidstone are so laid that they are much more likely to act as ventilators for the main sewers which flow through the lower part of the city, than those which flow through the central or non-infected district. The conclusion to which he comes is that under the conditions, it was most essential that the investigations, whether concerning the epidemic at Maidstone or elsewhere, should not be limited to the water-supply, for while, naturally, it is first necessary to discover what is the primary cause of the epidemic, so that practical measures may be taken during the emergency to do away with the same, it would be folly to imagine that having done this much no further measures need be adopted, for a town, like a patient, is composed of individual parts which together form the collective whole. Some are strong and wholesome, others are weak and susceptible to disease, and, as the *Lancet* writer says, the duty of sanitary science is to discover and remove the cause of this condition.

The Farleigh water-supply of Maidstone is in the hands of a private company. The fact occurs to us that the terrible epidemic in Duluth, Minn., occurred at a time when the water-supply was in the hands of a private company, and the officers of the company denied that their water-supply was the cause of the infection and refused to move in the matter. In this case it was known that the intake-pipe was not at a very great distance from the emptying sewer-pipe in the lake, although it extended out a much greater distance. The officers insisted that it was sufficiently far away to be perfectly safe. As the epidemic increased, the citizens took the matter in hand and investigated it for themselves, and lo and behold, they found a break in the intake pipe close to the shore, and at very little distance from the emptying sewer-pipe. There was naturally a political upheaval about it, and the city of Duluth now has its water-supply in its own hands and under the direction of its Health Commissioners.

While there was apparently no such criminal care-

lessness on the part of the Farleigh water-supply company, at the same time the occurrence should lead us to ask whether the water-supply of all cities should not be operated by the city, under the direction of proper health-officers.

THE PHILADELPHIA MEDICAL JOURNAL.

THE first number of the *Philadelphia Medical Journal* is at hand. Its appearance is pleasing, and its contents varied and interesting. The one new feature which is quite distinctive in a medical weekly is the method of abstracting articles from other journals. Instead of selecting leading articles, certain journals are chosen and brief abstracts of their entire contents are presented, after the now familiar method of the *Medical Review of Reviews*.

In its Announcement the declaration is made that "the Company is to be its own publisher, so that by sins neither of omission nor of commission can commercial interests influence a line of the reading columns. By the advice of experts of national reputation the *Journal* will seek to draw the line against all nostrums in our advertisement columns, in order that from cover to cover the best scientific and ethical standards shall be safeguarded."

This is, indeed, most commendable, and it will be interesting not only to medical editors, but also to the profession at large, to observe how this "band of experts" discriminate between "nostrums" and numerous proprietary preparations, some of which have already found a place in their advertising columns, and have thus received the stamp of their approval. In these iconoclastic days the birth of an ethical arbiter, such as the *Philadelphia Medical Journal* evidently aims to be, marks an epoch in the history of medicine.

THE MEDICAL NEWS cordially welcomes the new journal to the sisterhood of medical weeklies, and predicts for it the meed of success which its enterprise merits and its unquestionable excellence will command.

ECHOES AND NEWS.

Bubonic Plague in Bombay.—Despatches from Bombay report a recrudescence of the plague in the vicinity of that city. Many new cases are daily reported, and many deaths have occurred. Up to date 14,257 cases and 11,882 deaths have been reported in Bombay alone.

Higher Salary Desired.—The subordinate staff of the Paris Medical Faculty have sent to the Deputies and Senators a petition signed by sixty-four medical men asking for an increase of salary.

Bequests to Charity.—By the will of the late Charles H. Contoit, who recently died in New York City, the bulk of his estate, estimated to be worth over $1,000,000, is left to New York charitable institutions.

Pneumonia Transmitted by Parrots. — According to the Paris correspondent of the *British Medical Journal*, seventy cases of psittacosis (pneumonia transmitted by parrots) have occurred in that city and its environs since 1892.

A New Editor for the Columbus Medical Journal.—Dr. H. Harvey Reed has tended his resignation as president, editor, and manager of the Columbus Medical Publishing Company, and Dr. J. E. Brown has been elected editor and manager.

Chinese Medical Maxims.—"The physician who is sure of his diagnosis says little; he who is not sure talks much without being understood." "The greatest enemy to the health of men is woman; the worst enemy to the health of women is man."

Medical Colleges Must Give Bond.—In the State of Pennsylvania all medical colleges are required to give a bond of $1000 as a guarantee that no human bodies will be dissected except those which come to them through the regularly appointed legal channels.

Bequest to the Philadelphia Hospitals.—Mrs. Henrietta R. Fales Baker, whose will was recently probated in Philadelphia, left an estate worth $2,000,000. Should her son and daughter die without issue the whole estate will revert to the University of Pennsylvania and the Pennsylvania Hospital.

Dr. Reed's Appointment.—Dr. Harvey Reed has accepted the position of superintendent and surgeon in charge of the Wyoming General Hospital located at Rock Springs, Wyoming. This hospital is a State institution, and the building, when completed, will have accommodations for eighty patients.

Loomis Sanitarium for Consumptives.—The Building Department recently refused to approve plans for this hospital, soon to be erected in New York City, on the ground that they did not call for a fire-proof building. A writ of mandamus has been applied for to compel the department to approve the plans.

Polhemus Memorial Clinic.—The opening of this institution, which is situated on the southwest corner of Henry and Amity streets, Brooklyn, N. Y., took place on December 30th. The building provides luxurious accommodations for clinic patients, and lecture-rooms and an amphitheater for the use of the Long Island College Hospital.

Obituary.—Dr. Henry Parke Wilson recently died at his home at Baltimore, Md. Dr. Wilson was born in Work-

ington, Md., in 1827. He was graduated from Princeton College, and studied medicine in the University of Virginia and the University of Maryland. He settled in Baltimore in 1851, and practised medicine there until the time of his death.

Sanitary Inspection of Barber-shops.—The Metropolitan Barbers' Association of the State and City of New York have prepared a bill which will be presented to the Legislature in the near future. Among other things the bill provides for a sanitary inspection of all barber-shops and for the appointment of a board of inspectors, to be selected from the ranks of the Association.

A Question of Pronunciation.—A correspondent writes to *The Lancet* (London) pointing out the fact that the usual pronunciation of the word "angina" (an-jai'na) is incorrect. Etymology and metrical usage make it "an-ge'na," with the penult short. The editor of *The Lancet* adds that the 1886 edition of Smith's Small Latin-English Dictionary gives the latter pronunciation of the word.

Preventive Inoculation and Plague.—From the joint report of the recent epidemic plague in Portuguese India, presented by M. Haffkine and Surgeon-Major Lyons, the president of the Bubonic Plague Research Committee, it is seen that the preventive serum was employed with good effect, both as regards limiting the number of persons attacked and in decreasing the mortality. Especially good results were obtained when strong lymph was used.

Dr. O'Dwyer Ill.—The medical profession throughout the world will be pained to learn of the serious illness of Dr. Joseph O'Dwyer of New York, who has contributed so much to diminish the death-rate in laryngeal diphtheria by the invention of his now famous laryngeal tubes. Dr. O'Dwyer has been suffering from what he himself diagnosticates as tuberculous meningitis. His diagnosis has been concurred in by numerous professional brethren who have been called in. Dr. O'Dwyer himself admits the fatal nature of his illness.

A Naval Hospital Corps.—A movement is under way toward the organization of a naval hospital corps similar to that of the army. It is proposed that the corps consist of twenty pharmacists at $75 per month, five at $100; sixty-five hospital stewards at $60; thirty-five first-class hospital apprentices at $24; sixty hospital apprentices at $18; and that naval hospitals be established at Portsmouth, N. H., Chelsea, Mass., Newport, R. I., New York City, Philadelphia, Washington, D. C., Norfolk, Va., Pensacola, Fla., Mare Island, Cal., and Yokohama, Japan.

Dr. Roswell Park.—Our readers will be gratified to learn that Dr. Roswell Park of Buffalo, who has been abroad during his convalescence from a serious septic infection, has returned to his field of labor. While passing through New York City, he called at the editorial office of THE MEDICAL NEWS, and we can, therefore, assure his many friends from personal observation that although the doctor does not present the satisfactory picture of perfect vigor which characterized his former appearance, he gives evidence of being on the way to complete restoration of health.

New Hospital for Contagious Diseases.—The opening of the New York Hospital for Scarlet Fever and Diphtheria, at the foot of East Sixteenth street, took place December 30th. The hospital consists of two pavilions, forming the letter "U," each two stories in height, and built of pressed brick. The laundry and fumigating apparatus are in the center. A special feature is the solarium for the use of convalescent patients. It is situated on the south side of the building and has a wall of heavy plate-glass. There is also a roof-garden. The beds are of iron, the chairs and tables of agate, and the shelves of glass. The hospital was open for patients on the first of January. There are no free beds.

Dr. Sherow a Victim to Cocain Poisoning.—Dr. E. J. Sherow of New York died at his home New-Year's morning from the effects of an overdose of cocain. Dr. Sherow graduated from the College of Physicians and Surgeons of New York in 1890, and supplemented his medical education by hospital experience at the New York, and Nursery and Child's Hospitals. Four years ago the Doctor began treating himself with cocain for the relief of annoying nasal catarrh. Steadily the insidious habit grew upon him, and he became a victim of cocain. Aside from this, it is said his professional prospects were bright. The probabilities are that he took the fatal dose of the drug by mistake.

St. Louis Laryngological and Otological Society.—On December 27th the St. Louis Laryngological and Otological Society was formed, composed of those physicians of St. Louis who limit their practice to the treatment of diseases of the nose, throat, and ear. Dr. J. C. Mulhall was elected president; Dr. J. B. Shapleigh, vice-president; Dr. F. M. Rumboldt, secretary, and Dr. A. S. Barnes, Jr., treasurer, for the year 1898. Meetings will be held monthly, and it is expected that the scientific programs furnished will be highly interesting and instructive. While the membership is limited, the privilege of inviting professional friends is reserved to each member.

Filtration of Milk.—In several European cities, sand filtration of milk is employed at a central depot after its arrival from the country. The filters consist of large cylindrical vessels, divided by horizontal perforated diaphragms into five superposed compartments, of which the middle three are filled with fine clean sand, sifted into three sizes, the coarsest being placed in the lowest, and the finest in the topmost of the three compartments. The milk enters the lowest compartment through a pipe under gravitation pressure, and after having traversed the layers of sand from below upward, is carried by an overflow to a cooler fed with ice water, whence it passes into a cistern from which it is drawn direct into the locked cans for distribution. Milk thus filtered is not only freed from dirt, but the number of bacteria is reduced to about one-

third. In new milk the loss of fat is said to be very slight, but the quantity of mucus and slimy matter retained in the sand is surprising. The sand is renewed each time the filter is used.

SPECIAL ARTICLE.

EXAMINATION OF APPLICANTS FOR POSITIONS IN THE MARINE HOSPITAL SERVICE.

A BOARD of officers will be convened at Washington, D. C., January 25, 1898, for the purpose of examining applicants, for admission to the grade of Assistant Surgeon in the United States Marine Hospital Service.

Candidates must be between twenty-one and thirty years of age, graduates of a respectable medical college, and must furnish testimonials from responsible persons as to character.

The following is the usual order of the examination: 1. Physical. 2. Written. 3. Oral. 4. Clinical.

In addition to the physical examination candidates are required to certify that they believe themselves free from any ailment which would disqualify for service in any climate.

The examinations are chiefly in writing, and begin with a short autobiography by the candidate. The remainder of the written exercise consists in examination on the various branches of medicine, surgery, and hygiene.

The oral examination includes subjects of preliminary education, history, literature, and natural sciences.

The clinical examination is conducted at a hospital, and when practicable candidates are required to perform surgical operations upon the cadaver.

Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur.

Upon appointment the young officers are as a rule first assigned to duty at one of the large marine hospitals, as at Boston, New York, New Orleans, Chicago, or San Francisco.

After five-years' service Assistant Surgeons are entitled to examinations for promotion to the grade of Passed-Assistant Surgeon.

Promotion to the grade of surgeon is made according to seniority, and after due examination as vacancies occur in that grade. Assistant surgeons receive $1600. Passed-assistant surgeons, $2000, and surgeons, $2500 a year. When quarters are not provided, commutation at the rate of thirty, forty, or fifty dollars a month, according to grade, is allowed.

All grades above that of assistant surgeon receive longevity pay, *i. e.*, ten percentum in addition to the regular salary for every five-years' service up to forty percentum after twenty-years' service.

The tenure of office is permanent. Officers traveling under orders are allowed actual expenses. For further information, or for invitation to appear before the board of examiners, address Walter Wyman, Supervising Surgeon-General, United States Marine Hospital Service, Washington, D. C.

CORRESPONDENCE.

ANSWER TO DR. WILLY MEYER.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: Please grant me sufficient space in your worthy paper to mention that I reaffirm my statement made in my article on "A New Method of General Anesthesia" regarding the doses in the administration of the Schleich mixture. My claims are based on personal experience which, although not very large, is sufficient to convince me of the correctness of my observations, and to prove that the use of such large amounts of the anesthetic as Dr. Willy Meyer states he uses is wholly unnecessary. Details of my observations will be presented at a later date. Yours very truly,

M. L. MADURO, M.D.

NEW YORK, December 24, 1897.

PRE-COLUMBIAN LEPROSY IN AMERICA.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: I read in your report of the recent Lepra Conference at Berlin that, "He (Virchow) considers that the mutilations observed in certain ornamental figures found on what evidently is Pre-Columbian pottery, point to the existence of leprosy on the American Continent before the Spanish discoveries. There is no other disease which could have produced the mutilations of the feet observed in the figures. The nasal mutilations point to lupus rather than to leprosy, but Professor Virchow called attention to certain faces in Professor Lassar's collection of wax models of Norwegian lepers which very closely resemble those found on the potteries."

This discussion was on my paper: "The Question of Pre-Columbian Leprosy in America." Your reporter, however, fails to give what Dr. Carrasquilla of Colombia had to say on the subject. This South-American doctor, who knows a great deal about South-American history and customs, very probably far more than Professor Virchow, as soon as he saw the photographs which accompanied my paper, said: "The clear cut of the nose and upper lip shown in the pottery faces, and the amputated feet represent punishment inflicted by the Incas for certain crimes." I think that this settles the matter. As Professor Virchow said, "No other disease could have produced the mutilations observed in the feet;" but the sharp sword of an executioner could.

Other mutilations I am inclined to consider as evidences of lupus and syphilis; yet, it is natural to think if the amputated nose and lip are the result of punishment, that the amputated feet are so, too. But then there are marks which point to disease, such as the prognathous jaws, the spinal curvature, the side of the face eaten away, etc., which appear in the amputated-feet images, at least in some of them.

Perhaps this will make Dr. Carrasquilla pause; but, if these signs lead us to suspect disease, they just as naturally make us reject the idea of this disease being leprosy. It may have been facial lupus, tuberculosis of the vertebræ, or syphilis. If leprosy had eaten off the feet, as

Professor Virchow thinks, it would at the same time have mutilated the hands. Now, the hands in all the images are perfect.

I will conclude in a few words: The mutilations shown by my photographs may represent punishment, and some of them lupus, etc., but, Professor Virchow to the contrary notwithstanding, *not leprosy*.

ALBERT S. ASHMEAD, M.D.

NEW YORK, December 26, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

THE ISOLATION OF THE CRIMINAL INSANE—AGAINST THE ESTABLISHMENT OF A FOUNDLING ASYLUM—PHILADELPHIA NEUROLOGICAL SOCIETY—LARGE CONTINGENT BEQUESTS TO PHILADELPHIA HOSPITALS—DR. F. P. HENRY FOR HEALTH-OFFICER—DR. G. S. WOODWARD APPOINTED A MEMBER OF THE BOARD OF HEALTH—IN MEMORY OF DR. HARRISON ALLEN AND DR. GEORGE H. HORN.

PHILADELPHIA, January 1, 1898.

THE State Board of Charities of Pennsylvania is making a determined effort to establish in this State, by an act of Legislature, a hospital exclusively for the treatment of insane convicts and the criminal insane, there being at the present time 118 of the former, and 158 of the latter class confined, under wholly unfavorable surroundings, in the various State penitentiaries. Between the insane convict and the criminal insane there seems to be a decided difference, according to the general sentiment of the public, which holds that the one is a person who, while insane, commits a criminal offense, while to the other is attached the stigma of criminality prior to the development of insanity. This fine point which is shared by the State law-makers, as well as by the laity at large has been in the past the stumbling-block which has thwarted the efforts of the Board and of others in favor of their project; and their attention at present is directed against this prejudice, in many quarters, of placing these two classes of lunatics in the same category, and in the same institution. The intention is to establish a moderate-sized hospital on the grounds of some one of the State penitentiaries, and to there carry out the efficient plan of caring for the "detained," we will say, insane, which has been so long in vogue at the New York State Hospital for the criminal insane, first at Auburn, and later at the present site at Matteawan.

A unanimous opinion against the advisibility of establishing a foundling asylum in this city was expressed last week at a meeting of several prominent citizens, held to consider this subject, about which considerable agitation is going on in other quarters. Physicians, the law, the clergy, and the laity were represented at this meeting, and declared the founding of such an institution inexpedient, lowering to the general moral standard of the community, and entirely to be deprecated. It remains, however, to see what effect, if indeed any, this protest will have upon the growth of the project. Could the helpless babes abandoned on the vacant lots, or heartlessly consigned to some one else's doorstep have a voice in the matter, which would they prefer, a childhood passed in the precincts of the city almshouse, or the training and care and comforts of an institution devoted to their welfare? And under which of the two surroundings will the name, bastard, be sooner lost?

At the last meeting of the Philadelphia Neurological Society, held December 20th, Dr. James Hendrie Lloyd exhibited a case of astasia-abasia, occurring in a hysterical woman, who had recently undergone a gynecologic operation. The patient had been confined to bed under the delusion that she was paralyzed, but had improved under suggestive therapeusis, to such an extent that she is now able to walk without support, although incoordination of gait and station was still present. Dr. D. L. Edsall reported, by invitation, a case of dissociation of sensation of the syringomyelic type in Pott's disease. The patient, a boy, in early adolescence, suffered from caries of the second, third, and fourth cervical vertebræ, together with the manifestations of analgesia, thermo-anesthesia, and the preservation of tactile sensation—the dissociation of sensation generally believed to be a characteristic symptom of syringomyelia. The speaker expressed his belief that the lesion causing these symptoms was an intraspinal tumor, probably associated intraspinal tubercle. Dr. W. E. Hughes exhibited, by invitation, a tumor of the pituitary body, and also described a similar case. One of these neoplasms proved to be a small lymphosarcoma; the other a large carcinoma. It is of interest to note that symptoms of acromegaly were absent in both cases. Dr. A. A. Eshner further discussed an interesting case of meningitis which had been presented before the Society at a previous meeting, provoking at the time considerable discussion of the question of the differential diagnosis between basilar meningitis and posterior sclerosis. In the case in question *post-mortem* examination showed that death was due to cerebellar hemorrhage, following a diffuse meningoencephalitis. Dr. H. M. Schreiner reported an instance of arsenic neuritis, in a choreic girl ten years of age, who, after the administration of moderate amounts of the drug, developed widespread paralysis.

A contingent bequest of the late Henrietta R. Fales Baker bequeaths, in event of the death of her son and daughter without issue, the sum of $2,000,000 to the Pennsylvania Hospital, to erect and maintain a hospital to be known as the Fales Hospital for Surgical and Infirmary for Chronic Diseases. The University Hospital is to receive, under the same terms, $200,000, and the University of Pennsylvania $300,000 to endow professorships in the medical and scientific departments.

Dr. Frederick P. Henry, Professor of Practice of Medicine in the Woman's Medical College of Pennsylvania, is being urged for the position of Health-Officer of this port by those interested in the elimination of this important office from city politics, and it is hoped that Governor Hastings will act favorably on the recommendations being made in favor of Dr. Henry's appointment. The resignation of the former incumbent of the office, Theodore B. Stulb, has been "accepted" by the Governor.

Dr. George S. Woodward has been appointed by the Mayor to fill the vacancy in the Philadelphia Board of Health, caused by the death of Dr. William H. Ford.

A special meeting commemorative of the late Doctors Harrison Allen and George H. Horn, the two distinguished scientists, was held by the Academy of the Natural Sciences on December 31st. Addresses were made by Doctors Daniel G. Brinton, Edward S. Nolan, Professor John B. Smith of Rutgers College, and others.

The total number of deaths occurring in this city for the week ending December 25, 1897, was 396, of which 106 were in children under five years of age. Deaths from diphtheria numbered 24; from scarlet fever, 2; and from enteric fever, 15. The general health of the city is fair, and the number of new cases of zymotic diseases is on the decline, as compared to previous weeks reported.

The annual report of the Registration Division of the Bureau of Health for the year 1897 shows that the total number of deaths in Philadelphia last year was 22,735, or a ratio of 18.72 per thousand inhabitants. This proves to be the lowest annual death-rate recorded here since 1879, when the ratio was 17.37 per thousand. During the past year there were 1231 deaths from diphtheria, or an increase of 369 fatal cases over 1896; 282 deaths from scarlet fever, an increase of 221 over 1896; and 401 fatal cases of enteric fever. Pulmonary tuberculosis caused the death of 2388 persons, while the victims of influenza, which was not considered to have been especially prevalent during the last twelve months, numbered 160. The past year, among other things, witnessed 20 homicides and 143 suicides within the city limits.

OUR BERLIN LETTER.

[From our Special Correspondent.]

LECTURES TO THE UNIVERSITY STUDENTS OF ALL DEPARTMENTS ON "THE SIGNIFICANCE AND PROPHYLAXIS OF VENEREAL DISEASES"—THE THERAPEUTIC INFLUENCE OF CONGESTION AND INFLAMMATION—UNCOOKED FISH AND PARASITIC AND MICROBIC DISEASES—NOMENCLATURE OF BACILLI AFTER VARIOUS DISCOVERERS.

BERLIN, December 31, 1897.

PROFESSOR LASSAR is at present delivering the best-attended lectures at the University of Berlin. Nearly a thousand students of all faculties, mainly, however, non-medical men, will be found in the largest lecture-room of the principal University building any Tuesday evening, listening with every appearance of the greatest interest. The subject is "The Significance and Prophylaxis of Venereal Diseases." These lectures have now been given during the past three years, and the opposition manifested toward them in certain university circles before their institution and during the first months, when they were on probation, has faded away before the evident beneficial effect of accurate knowledge on subjects of such immense practical importance.

There is no danger, in the present state of our knowledge of venereal diseases, that "familiarity will breed contempt." Additions to our knowledge during the past fifteen years have practically revolutionized opinions as to the results of venereal infection of whatever kind. The significance of venereal diseases has become much more comprehensive, and the idea that they are a passing event in the life of mortals, that, like the diseases of childhood and colds in the head which nearly every one must go through and which almost never have any serious consequences, is now entertained only by those who are not abreast of the times.

No better sermon could be preached to the ordinary young man thrown for the first time on his own responsibility amid the temptations of a great city, for universities, fortunately or unfortunately, are, in our day, situated in large cities, than the inculcation of a clear, succinct idea of the present state of medical knowledge with regard to venereal diseases and their immediate and remote consequences. It would almost seem to be the duty of university authorities to furnish the opportunity for the acquirement of such knowledge as a safeguard of health quite as much as the encouragement of athletics.

Here university responsibility in the matter has been squarely faced and met by the establishment of a special lectureship, supported by an extraordinary government provision for the purpose. The matter is excellently placed in Professor Lassar's hands. The interest has never waned, and there is always, as previously mentioned, a large and appreciative audience at the lectures.

No exaggeration is required to make the fearful consequences of venereal disease clear, and there has been, on the other hand, no mincing of matters in the lecturer's descriptions. The lectures are illustrated by stereoscopic pictures, and in the first lecture of the course, for example, after the diplococcus of Neisser, as found in a recent case of gonorrhea, had been exhibited, the same organism from a case some fifteen years old, where its existence was absolutely unsuspected by the patient, was shown. The conjugal infection that had followed all unwittingly, and the consequent innocent suffering involved was dwelt upon. Some of the statistics of serious diseases of the female pelvic organs which have been traced to such infections were given. The personal experience of even the youngest of the men was appealed to as furnishing examples of young and healthy women falling victims to insidious disease shortly after marriage, the root of the trouble, not being some obscure woman's ailment, insidiously developing no one knew how, but, in reality, an infectious remnant of a husband's gonorrhea, existing very often without his knowledge.

To most young men such information comes as a distinct surprise. Information of the most varied kind, from quacks and mountebanks, from advertisements, and so-called medical books he has had, but the evident purpose to exploit his failings has led him to distrust it all. Plain talk from a man thoroughly conversant with the subject, utterly trustworthy and disinterestedly solicitous, he heartily welcomes.

It is an interesting study to watch the students' faces while they hear such home truths as that a gonorrheal infection may continue many years, or may finally end fatally in involvement of important membranes, or that most of the so-called women's diseases, with their necessitated mutilating therapeutics, and 80 to 90 per cent. of the blindness in the world, is the result of innocently acquired gonorrheal infection. Such information puts in a

new light a host of things which before seemed trivial, and shows their real importance. When to all this is added the fearful significance of syphilis in the development of the hopelessly incurable nervous diseases, from the apoplexies to paresis in middle life to tabes and the varied results of arterial degeneration in later years, a wonderful lesson is taught. A lesson, too, that under present circumstances is owed to every young man; for the unknown dangers of life, with their inevitable consequences, are plentiful enough already without leaving him in the dark on a subject like this, where definite knowledge is ready at hand and prophylaxis a comparatively simple matter.

Such a course of lectures would be eminently suitable for our large American universities. That they would be well attended no one would think of doubting. That they would do great good seems just as indubitable. The candid admission, however, of the imminence of the danger to young men is not in accord with Anglo-Saxon principles generally in such matters, and so, it may be supposed, the suggestion of such a thing to most university faculties would be met by prompt discouragement. Some time, however, in the near future the wisdom of such a course of action will dawn upon educators who are sincerely interested in the student's welfare, and then young America, too, will have the chance to learn these important truths.

Dr. Hamburger has just published some very interesting investigations of the influence of congestion and inflammation on bacterial life (*Deutsche Med. Wochenschrift*). He starts with the observation, which has now been confirmed upon all sides, that patients with mitral stenosis very seldom acquire tuberculosis of the lungs; while, on the contrary, those affected by congenital pulmonary stenosis almost invariably are ultimately carried off by this disease. He finds that, while jugular serum—*i. e.*, the serum of blood drawn from the jugular vein—is much more bactericidal than ordinary serum taken from blood-vessels at the periphery of the body, carotid serum (from the internal carotid) is much less bactericidal in character.

He has found, too, that when CO_2 is added to ordinary serum its bactericidal properties are much increased. This procedure adds, of course, to the alkalescence of the serum. He calls attention to the fact, which Behring and Cantani and other distinguished serum-therapeutists have already pointed out, that increase of alkalescence in animal serum increases its protective power.

Dr. Hamburger thinks that there is here the explanation of certain phenomena of inflammatory processes, and points out that the congestion incident to these is perhaps a protective reaction on the part of Nature which may well deserve imitation in local infections. He finds, too, that in such processes there are changes in both red and white blood-cells, notably a swelling and irregularity of outline which is accompanied by the giving off of CO_2, which is obviously, to his mind, only another phase of this natural protective process.

Among the varieties of food which have been the subject of investigation, fish has not had as important a place as some others. The epidemics of typhoid fever which have occurred during recent years have called attention to the fact that shell-fish constitutes almost the only animal article of diet which is now consumed uncooked. The necessity for extreme caution and the advisability of eating this variety of food only when cooked, unless one knows the origin, just as with water, is being insisted upon.

Attention has also been called to the fact that there are certain forms of smoked fish often consumed uncooked which are equally liable to be infected with the morbid element of various infections and communicable diseases, and that the process of smoking does not destroy the vitality of the unwelcome additions to the fish. Certain of the Baltic provinces of Germany have had quite a few cases of fish tapeworm, bothriocephalus latus, and some scattered cases throughout the Empire have been observed as the result of the more careful diagnostic methods of recent years. A note of warning has recently been sounded, and it would seem as though fish will soon come in for as careful government investigation, here in Germany at least, as do other animal foods.

The nomenclature of bacilli does not grow more satisfactory as time goes on and the field widens. More than one bacteriologist has lately been outspoken in the hope that a botanic classification of bacteria may soon replace the personal nomenclature which is so utterly unscientific and so varying under different circumstances. It is really the general practitioner and the specialist in other lines who have just cause for complaint. It is they who find it more than annoying, for it is often positively confusing. The calling the bacillus of tuberculosis Koch's bacillus may seem unpardonable enough to those who know better, but it has been known to occur even here. In a recent work on laryngology the bacillus of typhoid fever is called Gaffky's bacillus, with never a word of Eberth. The honor of having their names attached to the microbes of diphtheria and pneumonia is divided among four men, while the world knows that there are least four others, one of them an American, who equally deserve the honor. This faulty method will continue, it may be persumed, until, as in anatomy, an organized effort at systematization will have to be made, and then the adopted nomenclature will be as slow in finding its way into general use as have the results of the very meritorious effort of the anatomic committee in the same direction. Here, meantime, every step toward a purely scientific classification and nomenclature from the botanic standpoint is receiving deservedly widespread encouragement.

IMMEDIATE REDUCTION OF ANGULAR DEFORMITY OF THE SPINE—PREVENTION OF ENTERIC FEVER—PNEUMOTHORAX OF SOME MONTHS' DURATION CURED BY FREE INCISION—MECHANOTHERAPY OF MOVABLE KIDNEY—HERNIA OF THE ABDOMINAL CICATRIX AND THE OPERATIONS FOR ITS CURE—EMPYEMA OF THE ANTRUM OF HIGHMORE.

The Clinical Society at its meeting of November 26th continued the discussion of Calot's paper on *immediate*

reduction of angular deformity of the spine. Those members who expressed themselves as opposed to this operation base their objections chiefly on theoretic grounds, and besides, claim that the good results reported are of too short a duration, to enable the deduction of safe conclusions. CLARKE insisted that it is bad policy to keep a patient in a plaster jacket, as Calot's plan necessitates. Those who advocated the operation pointed to the success which Calot has had in more than 600 cases. THOMAS said that the theoretic objections that such treatment might produce (1) paraplegia, or (2) abscesses, or (3) dissemination of tubercle have all been proved to be groundless. Only one objection remains, *viz.*, that Nature cannot fill the "gap" with new bone; but as she is quite able to accomplish this in other bones in which surgeons have caused a solution of continuity, there seems no reason to doubt her ability to do the same in the spine.

At a meeting of the Royal Medical and Chirurgical Society, November 23d, POORE opened a discussion upon he *prevention of enteric fever*, by stating that the contagion of enteric fever is contained in excreta, and may gain access to the bodies of the healthy by means of drink, food, or inspired air. Records were given of forty-six instances, occurring during the last thirty years, in which epidemics followed contamination of public water-supplies. Attention was called to the possibility of pollution, often facilitated by the bad practice of laying water- and sewer-pipes side by side, neither being open to inspection. Pollution at the periphery is liable to occur whenever a tap is left turned on, and a vacuum thus produced in the supply-pipe by intermission of the supply, so that gas, or water, or even solids, may be drawn back into the house-pipe, Thus, in one house the water-pipe at certain times yielded blood, which was sucked into an open tap in a slaughter-house next door. It must be remembered that in big towns there are many foul places other than water-closets over which there may be open taps. A few of the practical remedies suggested were: the maintenance by water companies, just as by large dairies, of a staff of chemists and bacteriologists; the separation of water- and sewer-pipes, and the location of them as far as possible in subways; cremation of excreta in country places, or the scattering of this material upon suitable soils, when, under the influence of sun and rain, aided by frequent light plowing, such material soon becomes harmless. As enteric fever is preeminently a water-borne disease, the excreta from patients having it should never be mixed with water, as the property of water is to return to its source. There can be no purity of soil without tillage, and organic filth must be placed upon the humus to increase the food-supply, and not beneath it to endanger the water-supply. At present our population is silently taught that the only decent way to treat feces is to mix them with water to brew sewer-gas, and thus insure the aerial, as well as the aquatic, convection of enteric fever.

THORNE did not admit that the conclusions of Poore in regard to the danger of the present systems of water and sewage are correct, and in support of his position he quoted statistics to prove that the death-rate from typhoid fever is less than half of what it was under the old systems of wells and privies. No doubt the spreading of normal stools upon frequently tilled fresh soil in a short time destroys all enteric bacilli; but it has not been shown that this is a safe practice to follow in disposing of infected sewage. Experiments have shown that though typhoid bacilli will grow only a few days in sterilized virgin soil, they will grow 200 days in sewage-soaked soil which has not been similarly sterilized.

BOYCE made a plea for more thorough bacteriologic examination, which he regards as the real safeguard of a community from epidemics of enteric fever.

At a meeting of the Medical Society, November 22d, WEST read a paper on a *case of pyopneumothorax of some months' duration cured by free incision.* About four pints of seropurulent fluid were removed, and the patient rapidly improved, though a tube was kept *in situ* seven months. As a rule such cases are left alone from a belief that the lung is bound down by adhesions. The reader cited several cases to show that this view is by no means always correct. Another false notion is that pneumothorax is generally associated with tuberculosis of the lung, and that the pressure of the air or fluid in the pleural cavity will arrest the development of tubercle, a view absolutely without foundation, though it was once held in regard to serous or purulent collections in the chest. In short, the presence of air does not effect the principles of treatment in case of fluid in the pleural cavity.

BOWLES said that the position of the patient with the sound side upward is of great importance during anesthesia in pyopneumothorax. Two cases have been recently recorded, in each of which death followed the turning of the sound side of the patient upward to facilitate operative procedures, death being due to a flow of pus into the bronchial tubes of the sound lung.

ECCLES read a paper on the *mechanotherapy of movable kidney.* Sixteen patients were treated by means of "rest," with especial attention to abdominal massage and exercise during periods varying from two to eight weeks. Seven of these patients disappeared from observation; in one instance the treatment was a complete failure, but the remaining patients almost immediately improved, and five of them were greatly, and to all appearances, permanently benefited by abdominal massage, exercises, and the application of a pad and belt. It is of importance that the displaced kidney be replaced as early as possible and kept in its normal position. Replacement is best secured when the patient lies upon the sound side, flexes the thigh of the affected side acutely on the abdomen, and extends the arm of that side well above the head.

DORAN read a paper before the Harveian Society, November 18th, on *hernia of the abdominal cicatrix and operations for its cure*, in which he took the ground that such conditions may be most satisfactorily relieved by suture of the abdominal wall in layers, avoiding a too deep suture in the peritoneum, in which case this membrane may be everted and an actual hernial pouch produced. The edge of the rectus muscle should be included in the aponeurotic suture.

ROUGHTON read a paper on *empyema of the antrum*

of Highmore. The essentials of treatment were stated to be: (*a*) a removal of the cause by dealing with nasal or dental disease; (*b*) evacuation and drainage of pus; (*c*) antiseptic irrigation, and (*d*) removal of morbid tissue (when present) from the antrum. He advocated that an alveolar tube be fitted in every case. The points which SPICER regards as essential to the success of a radical operation are: (1) a large opening through the canine fossa; (2) thorough curettement of the diseased antral mucosa; (3) very free counter-opening from the nose into the antrum, and (4) no drainage apparatus (the air-blast sufficing to clear the antrum of pus until the mucosa is healthy). No bad results, certainly no sinking of the cheek, had occurred in any of his cases.

Berlin.

ADVANTAGES OF CELLULOID-TRICOT-CORSETS.

At the session of the Medical Society, on November 10th, JACQUES spoke of *the advantages of the celluloid-tricot-corset.* Celluloid has ordinarily been employed upon wide strips of mull in order to make a stiff corset, but there is danger, especially in the case of women having a large bust and small waist, that there will be parts of the corset which contain air-spaces. This can be avoided by using a very light tricot in the following manner: The cloth is first cut in squares large enough to reach conveniently around the patient. One such piece is stretched tightly about her, an easy process owing to the elasticity of the tricot, and carefully rubbed full of celluloid-gelatin, Another layer is applied and this again filled with celluloid-gelatin, and so on until the corset is sufficiently thick. After two days it is cut off and prepared with laces. If applied in this way the corset will be both elegant and durable.

At the session of November 24th, PLACZEK described a *case of uncomplicated paralysis of the serratus magnus.* The only history obtainable from the patient was that some months previously he had fallen from a ladder, jerking his right arm above his head. Soon after he had had pain in the right suprascapular region, which was ultimately followed by the paralysis. If the patient attempted to bring his arm from a horizontal position forward, the scapula fell away from the thorax like a flail. If an attempt was made to raise the arm to a vertical position it failed, unless the lower angle of the scapula was drawn outward, thus making good the deficient action of the serratus muscle.

PLACZEK also showed a patient who suffered from spasm of the masseter muscle. This patient was a locomotive fireman, and by reason of his occupation was subjected to sudden changes of temperature, increased by the habit of leaning out of the window. The patient suffered from neuralgia of the third branch of the fifth nerve, and with the attacks of pain. There usually was a contraction of the masseter muscles of both sides, the spasm ending with the mouth wide open. The attacks occurred about every five minutes.

At the session of the Union for Internal Medicine, November 22d, LOWENTHAL spoke of disinfection of the intestines. There are two methods of determining the efficacy of an intestinal antiseptic, one being the bacteriologic examination of the stools. This has proved absolutely unreliable. The other method is the chemic examination of the urine in order to determine quantitatively the presence of those substances which are due to intestinal putrefaction. Using this method as a test, Lowenthal made experiments with amyloform, a substance which yields formaldehyd if introduced into the alimentary tract. In the test cases the dose was gradually increased until formaldehyd could be demonstrated in the urine. The quantity of the products of intestinal fermentation in the urine were distinctly decreased by this means in spite of the somewhat constipating effect of the drug.

STRAUSS has made similar experiments with steriform, and BLUMENTHAL with itrol. Both of these observers reported inconstant results.

ZIEGELROTH spoke of the prophylactic value of periodic sweats. Recently, numerous investigations have proved that sweat contains pathogenic microbes. The speaker himself, by a comparison of the bacteriologic condition of water, before and after a patient had bathed in it, found that the water contained three times as many microbes after a sweat bath as after an ordinary bath. The advantages of such a bath before an operation are therefore plain, and serves an even greater purpose in stimulating cellular oxidation. Such baths are contraindicated in diseases of the heart and circulatory apparatus. They act as a specific in rheumatism, and while they may increase the symptoms of an attack of gout they improve the general condition of the patient. The specific gravity of the blood is the same before and after a bath, so that the blood is not changed by it. Two points should be carefully observed: first, the duration of the bath should not exceed fifteen to thirty minutes, and second, care should be taken to at once replace the fluid which has been lost by the sweating by copious draughts of water.

SOCIETY PROCEEDINGS.

THE NEW YORK CLINICAL SOCIETY.

Stated Meeting, Held November 26, 1897.

THE President, DR. FRANK W. JACKSON, in the Chair.

DR. B. FARQUHAR CURTIS read a paper, entitled

SOME EXPERIENCE WITH URETHROTOMY FOR STRICTURE.

The author said that in speaking only of urethrotomy he did not wish to be understood as believing in this operation to the exclusion of dilatation. The paper was devoted to a discussion of the results of operations performed with certain definite ideas in view as to treatment. The cases, though few in number, were much alike, and were all observed in hospital practice. The list included nearly twice as many external as internal operations, owing to the severity of the class of cases seen in St. Luke's Hospital. The operator had aimed to make the urethra of sufficient caliber to admit a No. 30 (French) sound measured with a bulbous bougie, which, as is well known, usually is two sizes smaller than a steel sound of the same num-

ber. The usual aseptic precautions were observed in all instrumentations and operations. Steel and soft rubber instruments were boiled. For the urethra, Thiersch's solution was employed, except in a few very foul cases, in which a 1-to-10,000 or even a 1-to-5000 solution of bichlorid of mercury had been used. As a rule it was necessary to incise the meatus, the incision usually being made on the floor of the urethra, although the roof and the sides were nicked when necessary. About half of the patients were operated upon under cocain anesthesia. Ill effects from the use of this drug were not observed, although the delay and the nervous excitement incident to the employment of local anesthesia prevented its use in many instances; it is necessary to retain the cocain solution in the urethra four or five minutes, and to wait as long again before beginning the operation. Failures with this method of anesthetization may generally be explained by too great haste. Cocain intoxication is the result of allowing the solution to remain in the urethra. Nitrous oxid gas is also a useful anesthetic agent in these cases.

The two dangers of internal urethrotomy are hemorrhage and sepsis. In none of the cases was hemorrhage alarming. When it had been free, he had employed a strip of muslin, one foot long, and as wide as the penis was long, torn at each end so as to make a many-tailed bandage. A couple of layers of gauze were wrapped around the penis and then bass-wood splints were applied, and finally, over them, the many-tailed bandage. It is, of course, necessary to loosen the dressing during urination. The foreskin must always be retracted before applying the dressing, else it will certainly swell badly. In only one or two cases had the severity of the hemorrhage made it necessary to insert a catheter into the urethra, and then bandage the penis. The perineal crutch had only been employed in one or two cases. Sometimes an ice-bag or a hot urethral injection of alum solution had been of value. The immunity from hemorrhage was doubtless due to the fact that the operation of internal urethrotomy had been restricted to the anterior five and one-half inches of the canal, and in a large proportion of the cases the wound extended only to a depth of three inches from the meatus. In those few cases in which chill and rise of temperature occurred, the administration of 10 or 15 grains of quinin two hours before the passage of a sound, prevented the chill and fever, so that it was not probable that very serious sepsis was present.

In one case, a fatal result, probably from auto-infection, occurred—the only death from internal urethrotomy in the speaker's experience. The case was that of an Italian, twenty-eight years of age, who was admitted to St. Luke's Hospital, December 8, 1891. He had had one attack of gonorrhea eleven years previously. No instrument larger than a No. 10 (French) sound passed down the whole length of the urethra. The urine did not contain albumin or sugar. After urethral irrigation for four days, internal urethrotomy was performed on December 12th. Bulbous bougie, No. 20, entered the meatus; No. 18 passed one-eighth of an inch; No. 12, five-eighths, and No. 10, five and three-eighths inches. The meatus was incised on the floor and roof, and the Otis urethrotome could then be passed four inches and a half. It was screwed up and withdrawn, and then bulbous bougie No. 26 passed. The urethrotome was again employed, and after this cutting, a No. 34 (French) sound passed into the bladder. A foul discharge then escaped, The operation continued twenty-five minutes, during which time eight ounces of ether was consumed. The patient rallied well, and the next morning appeared comfortable and in good condition. At 1.30 P.M. he passed eight ounces of urine with some bleeding and pain. This was followed by a rise of temperature from 99° to 102° F. He was at once given 8 grains of quinin, and at 4 P.M. his temperature was again 99° F. That evening he had severe pain in the region of the kidney after urinating, and then another chill, with a rise of temperature to 102° F. He passed seventeen ounces of urine mixed with blood during the twenty-four hours subsequent to the operation. The next morning he appeared flushed and restless, but without definite complaint. On the right leg, near the ankle, an emphysematous crackling was detected along the course of the veins. There was no redness, edema, or swelling at that time, and this was the only point of crepitation. Lead and opium applications were made to the part. The urethra was being regularly irrigated with Thiersch's solution. The temperature remained high, and sixty-three hours after the operation the man died. There was no redness, swelling, or unusual tenderness in the penis or groin. The autopsy showed nothing unusual in the urethra, but gas was found in the veins of nearly all the organs of the body. The kidneys were healthy. It seemed improbable that the infection took place at the operation, because the same technic and instruments were employed in another case on the same day without any untoward result. Considering the foul discharge behind the stricture, the theory of auto-infection of the wound seemed the most plausible. The speaker believed if the urethra had been opened through the perineum the man might have been saved, and this had been his principle of practice in similar cases since then. It was interesting to note that the strictures were situated in the anterior three and a quarter inches of the canal, where operations are generally considered trifling.

In regard to external urethrotomy, the principal objections to this procedure are as follows: The danger of hemorrhage, and the possibility of a troublesome fistula and the resulting confinement to bed. By the external operation at the present time is understood a short perineal incision made for the purpose of draining the urethra and bladder behind the stricture, but it is generally admitted that the strictures themselves are rarely situated in the region opened by this wound—namely, six or seven inches below the meatus. The perineal opening must be made when it is impossible to introduce instruments through the meatus to the bladder. It is also generally employed when the stricture is deeper than five and one-half inches, because of the danger of hemorrhage in such a deep-seated internal wound, and also on account of the danger of retention of the discharge and consequent sepsis. When cystitis is present the advantage of draining the bladder during a few days is obvious, and constitutes another in-

dication for the external operation. Again, if there is a foul discharge behind a narrow stricture, even though this is within two inches of the meatus, the perineal section should be employed. The longer confinement to bed is not a weighty objection to the operation. No matter how small and shallow the wound in the urethra may be, it is a wound which we are largely obliged to leave to itself during recovery, and hence the patient is safer in bed during a few days, even in the simpler cases. Moreover, the perineal section is chiefly advised for a class of cases which should be confined to bed because of the gravity of the lesion. The perineal operation is only difficult when performed without a guide, and in such cases internal urethrotomy is manifestly impossible. The difficulty arises only when no other operation is possible. The most serious objection is the possibility of a permanent or slowly healing perineal fistula. In a certain number of cases this is unavoidable, but they generally occur when drainage has been maintained a long time on account of a coexisting cystitis. Dr. Curtis endeavors to avoid fistulæ by very early removal of the tube when cystitis is not present. The external incision is generally indicated when it is necessary to divide a deep stricture, to find the urethra behind an impassable stricture, or to drain the posterior urethra. The tube should, therefore, be removed within a day or two, and the perineal wound lightly packed with gauze. If chill or rise of temperature does not follow the next urination the tube is no longer required. If fever occurs, the tube should be reinserted, and another attempt made within a few days to discontinue its use. The speaker had observed, in some instances, such rapid healing of the perineal wound that there was no leakage after the first week. Not infrequently cases are seen in which the perineal wound must be rather extensive in order to deal successfully with strictures, fistulæ, false passages, or other lesions. Such a wound may be almost closed with sutures, leaving, of course, a small opening posteriorly. The speaker has succeeded in closing permanent sinuses by means of the double-flap operation, although as a rule several attempts were required before success was achieved. The most serious difficulty in cases of impassable stricture is the location of the urethra without a guide—still one of the most difficult operations in surgery. The difficulty in passing these strictures is often due to the existence of false passages. In two cases observed by Dr. Curtis there had been extravasations of urine with complete sloughing of the perineal urethra. In one case there were many sinuses through which the patient urinated as from a watering-pot.

He has been able to subsequently observe only a few of his cases. Of those patients upon whom internal urethrotomy had been performed, twelve had been kept under observation, in four of whom relapse had occurred. Two had frequently used the sound during a period of two years and one-half, and a year and one-half respectively. The remaining six presented symptomatic cures. One patient who had had a stricture equaling in size a No. 16 (French) sound remained well without instrumentation two years, and finally died of phthisis. Another patient, on leaving the hospital, could pass sound No. 30 (French), and the same instrument could be passed two years later, although dilatation had been practised only during the six months after the operation. Still another patient, in whom there had been a stricture of No. 14 (French), could pass sound No. 30 (French) four years after the operation. One patient could pass a No. 28 (French) five years after the operation, although treatment had not been continued. Another, with an original stricture of No. 14 (French), could pass a No. 22 (French) sound eight years after operation, although there had been no subsequent treatment. Another, who had had a stricture of No. 22 (French), could pass a No. 26 (French) sound ten years after operation, dilatation having been practised three years. This patient had had two attacks of gonorrhea in the interval.

Dr. Curtis said that he had been able to follow the subsequent history of thirteen patients upon whom urethrotomy had been performed. It was found that in one relapse had occurred, and that in eight there had been symptomatic cure, but examinations of these patients were not made. Of those examined, one could pass a No. 32 (French) sound one year after operation; another a No. 26 at the end of two years, no sound having been passed for six months. Another patient passed steel sound No. 26 (French) to the ligament and No. 18 to the bladder six years after operation. Considering the severity of the cases and the common neglect of after-treatment, he thought these results were quite satisfactory. Of course, regular dilatation subsequent to operation would probably have produced still better results.

DISCUSSION.

DR. F. TILDEN BROWN said that the plan of controlling hemorrhage from the anterior urethra described in the paper was new to him, and he thought it a valuable suggestion. He fully endorsed the reasons given for making perineal section, yet, personally, he was inclined to resort to this operation more frequently, even in the more anterior strictures. The object is to secure perineal drainage for a *brief* time. It was his practice to wait until the first sound had been passed, usually on the third or fourth day, before deciding upon the removal of the drainage-tube. If the passage of the sound does not cause a disturbance, he withdraws the tube and carefully dresses the wound so as to secure healing of the deeper parts first. He has not had trouble with perineal fistulæ except in one case—a broken-down patient who had a suprapubic fistula of two-years' duration, a tuberculous testicle, and foul urine. Perineal drainage was maintained for some time, and a good deal of broken-down material was discharged through the fistula. A very simple operation was eventually sufficient to completely close the fistula.

The speaker referred to a patient who had worn a silver catheter continuously twenty-eight years, because of a traumatic stricture and severance of the urethra. The wound had at first been sutured, and subsequently a perineal operation performed, but the man had finally been advised to wear a catheter permanently. The stricture

was found to be at four and a half inches, but owing to the small size of the penis it was deeper than would have been the case in an ordinary adult man. A perineal incision was made, long posteriorly, for drainage. The anterior part of the incision opened the way to the stricture, which was very short. The mucous membrane over the stricture was cut transversely and laid back anteriorly and posteriorly. The dense layer was next dissected out from one edge of the longitudinal incision to the other, and the mucous membrane sutured together. A drainage-tube was inserted posteriorly, and kept in place eight or ten days. The man made an excellent recovery, and is now passing sound No. 32 (French) upon himself.

Regarding the occurrence of chill and fever in these urinary cases, Dr. Brown said that he believed that some cases of this kind cannot be explained on the theory of sepsis; they seem to be due rather to a nervous reflex. One great advantage of the perineal operation is that it admits of treating a contracted condition of the posterior urethra, not uncommonly found in old men.

DR. L. BOLTON BANGS said that he was quite in accord with the reasons presented in the paper for the performance of external urethrotomy. In his own practice he rudely grouped strictures into those of small caliber, those of large caliber, and traumatic strictures. Unless there is some emergency requiring it, he does not perform any cutting operation upon a urethra from which there is a discharge, no matter whether it is gonorrheal or due to some mixed infection. He agreed with the reader of the paper regarding the treatment of strictures of small caliber, but he makes it a rule to paint the posterior urethra, from the bulbomembranous junction back to the neck of the bladder, with a solution of nitrate of silver. This coats the urethra with an albuminous substance, prevents infection, and renders the urethra less sensitive for a number of days.

Regarding the treatment of strictures of large caliber, Dr. Bangs said that he believed there were many of these cases in which an operation is not required. In every case the mucous membrane is diseased, and, irrespective of stricture, one would have to first treat the affected mucous membrane. It is his rule to measure the urethra at intervals of a few months, meanwhile treating the lesions of the mucous membrane. In this way he determines the necessity for operation by the degree of contraction. If this plan were followed, it would be found that fewer strictures of this variety require operation. Dr. Bangs exhibited an endoscopic picture of the urethra of an old man who had not had urethritis since his boyhood, and who had been operated upon most zealously by a skilful surgeon, but without relief. Two or three distinct ulcers were revealed by the endoscope, and then it became an easy matter to apply successful treatment.

DR. MURRAY said that he personally resorts more and more to external urethrotomy, never trusting to internal urethrotomy when the stricture is below four or four and one-half inches from the meatus. If it is fairly tight, he always does an external urethrotomy. In the removal of the tube he is governed entirely by the condition of the bladder, but believes in as speedy removal as possible. Regarding the fatal case cited in the paper, he doubted very much if it were an example of auto-infection, and in this connection he agreed thoroughly with the criticism made by Dr. Curtis himself regarding the better result that would probably have followed perineal drainage.

DR. CURTIS, in closing the discussion, said that he usually passes a sound twenty-four or thirty-six hours after the operation, and then not again for a week. After this they are passed at intervals of a week. It seemed necessary to him to pass the first sound before the wounded surfaces have a chance to unite. He has had no case of tight stricture which seemed suitable for resection, nor any of large caliber, except the one case in which a No. 22 (French) sound could be passed. This patient, however, had strictures extending from the meatus to a point five inches backward. It seemed to him impracticable in a hospital service to postpone operative work until the mucous membrane behind the stricture has been put in a healthy condition, for the patient would often have to be kept under constant observation many months. Of course, if there is a profuse purulent discharge, the operation would have to be postponed for a time, but even then it is difficult to treat the condition until the stricture has been divided.

APPENDICITIS AND PERITONITIS WITH LOW TEMPERATURE.

DR. A. J. MCCOSH referred to a case, seen that afternoon—a young man who had had rather severe abdominal pain for about eight days, and had frequently vomited. The temperature had not been below 98° or above 99° F. He had been able to take a short walk the day before. He had been freely purged. When seen by the speaker at 3 P.M. the patient seemed to be seriously ill. A diagnosis of general peritonitis due to appendicitis was made. The beliy was quite tense; the temperature was 98° F., and the pulse 110. The patient had been very carefully watched by a good physician and nurse, yet he had not been considered a sick man, because he had not had fever. He was operated upon at 5 P.M. About ten separate pockets of pus were found, holding, in the aggregate, three or four pints of thin, watery, and very offensive pus.

THE PRESIDENT asked if the surgeons could furnish any points which would aid in the early diagnosis of these serious cases.

DR. MCCOSH replied that vomiting and regurgitation of gas whenever pressure was made upon the abdomen, together with the general appearance, are perhaps the signs of most value.

DR. FRANK HARTLEY said that the increasingly rapid pulse, rigidity of the recti muscles, and a general cyanotic appearance are fairly reliable indications of the gravity of the condition. Many cases run a serious course without any marked rise of temperature. Many laborers work in the streets up to the day before coming to hospital, and yet the appendix is found to be gangrenous. The rise of temperature seems to depend chiefly upon the amount of absorption of septic material.

CASES OF REMARKABLE SUBNORMAL TEMPERATURE.

DR. A. ALEXANDER SMITH said that during the night of November 22d a patient had been admitted to Bellevue Hospital with a temperature of 91.4° F. There was some doubt about the accuracy of this record, so it was taken with four thermometers. The only complaint made by the patient was that he thought he was freezing to death. He had a very disseminated pulmonary tuberculosis, and also nephritis. He was placed in an improvized incubator, and his temperature gradually rose until, at the end of twelve hours, it reached 102° F. and his pulse 84. His pulse on admission had been 64. At no time was the pulse over 100. When the temperature reached 98° F. he became very bright, and expressed himself as feeling well. After reaching 102° F., it gradually dropped back to 96° F. He lived twenty-nine hours and forty-five minutes. An hour and a half before death the temperature was 98° and the pulse 72. The autopsy confirmed the diagnosis.

A few weeks ago a patient had been admitted during the night to the same hospital with a temperature of 90° F., as determined by three thermometers. He made the same complaint as the other man, and under the same treatment his temperature gradually rose. He also had pulmonary tuberculosis and nephritis, but the autopsy showed, in addition, a small cancerous deposit in the head of the pancreas. Both patients, of course, had been living under the most unfavorable conditions, particularly as regards nutrition.

DR. WALTER MENDELSON said that while an hospital interne he had seen a man who was admitted during the summer with a temperature of 90.5° F. The patient was rather dazed, but seemed otherwise healthy. It was ascertained that he had had nothing to eat for a week. Food soon restored his normal temperature, although during the week after entering the hospital there was a tendency for the temperature to fall to 97° or 98° F. As the patient recovered, it was observed that his mental condition was not normal, although possibly this had existed previous to the illness in question.

REVIEWS.

A TEXT-BOOK OF PRACTICAL THERAPEUTICS, with Especial Reference to the Application of Remedial Measures to Disease and Their Employment upon a Rational Basis. By HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia, etc. With special chapters by DRS. GEORGE E. DE SCHWEINITZ, EDWARD MARTIN, and BARTON C. HIRST. Sixth edition, thoroughly revised and largely rewritten. Philadelphia and New York: Lea Brothers & Co., 1897.

THE eminent success of Dr. Hare's book on therapeutics is evidenced by the appearance of the sixth edition within seven years. This is to be attributed somewhat to the excellent arrangement of the subject-matter, the first part of the work dealing with therapeutic agents of recognized worth, the second containing the principal diseases, with a brief description of their pathology and symptomatology and their treatment in full. The present edition has been brought fully up to date and includes a full discussion of diphtheria antitoxin and of the newer remedies whose usefulness has been proven. Therapeutic measures of a non-medicinal nature are fully considered, and include cold, heat, mineral springs, and diet-lists.

The present edition will undoubtedly meet the same kindly fate as its predecessors, for the work is one of the few books which are really of value to the physician in his daily work.

THE CARE AND FEEDING OF CHILDREN. A Catechism for the Use of Mothers and Children's Nurses. By L. EMMETT HOLT, M.D., Professor of Diseases of Children in the New York Polyclinic, etc. Second edition, revised and enlarged. Flexible cloth; 104 pp. New York: D. Appleton & Co.

IN the second edition of this practical little work the author has preserved the form of question and answer of the first edition. While this makes the book much less readable, clearness and simplicity are gained thereby, and it has the further advantage of making it easy to find quickly any given point to which reference is desired. If put in the hands of the mothers of young children, this book will serve not to take the place of the doctor, but to make his visits and advice pleasanter and more profitable for both parties.

THERAPEUTIC HINTS.

For Whooping-cough tussol is recommended in doses of ⅙-grain, for an infant one month old, to 8 grains for a child of five years. It may be administered in raspberry syrup one to three times daily.

For Tabetic Neuralgia.—

℞ Malacini . . . . . ʒ iss
Sod. bicarb. . . . . grs. xlviii.
M. F. Chart No. xii. Sig. One powder two to four times daily.—*Kuthy.*

To Remove Warts painlessly and with avoidance of scars apply a supersaturated solution of bichromate of potassium once daily.

Destruction of Small Vulvar Vegetations may be accomplished by the repeated application of the following powder after the parts have been bathed and well dried:

℞ Pulv. sabinæ, Iodoformi, Ac. salicylic. } aa . . . . . ʒ ss.
M. Sig. External use.

Ichthyol Applied to Anal Fissures, in conjunction with dilatation of the sphincter muscle under cocain anesthesia, is said to act efficaciously, not more than ten treatments being requisite to effect a cure in recent cases.

For the Bites of Poisonous Insects it is recommended to paint the wound with pure ichthyol, or in case swelling and inflammation have occurred, apply ichthyol plaster, and adminster the drug internally in 10-drop doses in spirits of ether.

ORIGINAL ARTICLES.

COUGH DUE TO LESIONS OF THE NOSE AND THROAT.

BY WILLIS S. ANDERSON, M.D.,
OF DETROIT, MICH.;
LARYNGOLOGIST TO HARPER HOSPITAL POLYCLINIC; ASSISTANT TO THE CHAIR OF LARYNGOLOGY IN THE DETROIT COLLEGE OF MEDICINE.

THE physician is frequently called upon to treat the symptom cough, and to do so intelligently an accurate idea of the many different lesions capable of producing this disagreeable symptom is necessary. In diagnosis, cough is too often associated with diseases of the chest, and we are prone to forget that it may be dependent upon a lesion remote from the lungs. It is the unusual causes of cough, especially those dependent upon pathologic changes in the nose and pharynx, to which I wish to call attention. If the usual explanation be accepted, irritation of the branches of the vagus nerve must be regarded as the principal factor in the production of cough. When the general distribution of the branches of this nerve and their frequent communications with others are recalled, it may be readily understood how lesions of many different organs may give rise to reflex cough. Those who are accustomed to examining the nose, throat, and ear will have noticed how frequently a reflex cough is excited by the examination *per se.*; the introduction of an aural speculum is often sufficient to excite it. The explanation of this phenomenon is simple, when it is remembered that the auricular branches of the vagus are distributed to a portion of the auditory canal. Sprays and applications to the nares frequently provoke a cough, which varies in character in different individuals. We are indebted to John Mackenzie for calling attention to the fact that irritation of the nasal chambers is one of its causes. He found that certain areas in the nose, when irritated, gave rise to the symptom in question. These areas are the inferior and middle turbinate bodies and that portion of the septum opposite the posterior end of the inferior turbinate. So commonly are lesions of these areas the cause of the cough that they may be considered the nasal areas of reflex cough. In like manner, examination of the pharynx frequently produces the same result.

If it is true that the mere touching of these various surfaces causes this symptom, then it should certainly be expected as a regular accompaniment of lesions in this portion of the respiratory tract, and so it is found that it is frequently caused by hypertrophic rhinitis, and can only be relieved by curing the nasal affection. It is not usually a concomitant of a recent hypertrophy of the anterior portion of the inferior turbinate, but is frequently caused by the same pathologic lesion of the posterior end of the same structure. This condition may be permanently relieved by removal of the hypertrophic tissue or by its destruction with the galvanocautery. Hypertrophy of the middle turbinate is often the cause of the same symptom. The trouble may be due to hypertrophy of the mucous membrane alone, or to a thickening of the bone itself. If the enlargement, in either case, is sufficient to press against the septum, or nearly to occlude the nares, a train of disagreeable symptoms, of which cough is one, will be manifested. In many cases this condition is a troublesome one to relieve. When simple hypertrophy exists the symptoms may often be removed by cleansing and astringent sprays, followed by the application of menthol, grains v-x to ℥i of albolene. In true hypertrophy, the galvanocautery may be carefully employed with good results, or in case the original lesion has undergone polypoid degeneration the cold snare will be found to be of special service. When the bone is thickened it is often necessary to saw off a portion. This is often a very difficult operation, especially when the space in which the operation is to be performed is small and the field of operation very sensitive. In spite of the use of cocain the pain is usually severe, and hemorrhage interferes with the view. Care should be taken not to destroy more of the mucous membrane than is actually necessary, as the resulting cicatrix is sometimes a source of irritation, occasionally leading to symptoms almost as disagreeable as those on account of which the operation was performed.

Various observers have reported many cases of persistent cough due to fibrous and mucous polypi. The etiology of these growths is not well understood. These have been carefully studied by Zuckerkandl, who, in his admirable work, "Normal and Pathological Anatomy of the Nasal Cavities," gives a number of plates showing them to orginate, in a large majority of cases, around the ostium maxillare, under the middle turbinate. They push out from

the middle meatus and fill the greater portion of the nares, and may even hang down into the nasopharynx. They may be single, more frequently multiple, and may involve the accessory sinuses of the nose. Asthma and hay fever, with their accompanying coughs, are frequently dependent upon polypoids. There is but one treatment, and that is the removal of the growths. After this has been accomplished the stumps should be cauterized to lessen the danger of recurrence. The results of this treatment are often very gratifying, yet prognosis must be cautious, as in some cases there is an underlying neurotic element which resists all treatment. It has been the experience of the writer that in but few cases of asthma and hay fever of long standing can a permanent cure be obtained by treating the nasal cavities alone; but in the large majority a marked improvement follows, and in some, a complete cure. Of the other lesions of the nose which may cause cough, spurs and deviations of the septum are probably the most important. Deviations of the septum are estimated to be present in ninety per cent. of all adults, and spurs are commonly found. When these conditions present, the rhinologist must decide as to the advisability of operative interference. It seems to the writer that too many of these operations have been performed during recent years. There are many cases in which a moderate deviation of the septum or a small spur does not give rise to any symptoms. There are other cases with an S-shaped deviation causing an apparent stenosis, but on more careful examination one can satisfy himself that in spite of the irregular and tortuous channel the patient has a fair breathing space. In other cases there is present such a marked deviation of the septum as to occlude one side, and yet, in spite of the exaggerated lesion, there is no complaint from the patient. In any of these types cough may or may not be presented as a symptom. One ought not to be too hasty in attempting operative interference for the relief of cough, or, in fact, for the relief of any other symptom, unless there is an evident connection between the local disease and the symptom.

The surgical treatment of these lesions is one requiring judgment and careful study of all the factors of each individual case. If operations upon the septum were never followed by a disagreeable train of symptoms it would be a different matter, but the practical fact is, that the condition often returns, or a train of annoying symptoms follow, due, in some cases, to a resulting perforation, or to the cicatrix which forms at the site of operation, or, as may possibly happen, to the formation of adhesions between the septum and the outer wall of the nose. I do not wish to take the position that operative treatment is never indicated, but feel that a careful study of all cases and a consideration of the probable condition after the lapse of a few years will reduce the number in which an operation is apparently justifiable.

Lymphoid hypertrophies of the nasopharynx are a very frequent cause of cough, especially in children; and although a very common affection, its importance does not seem to be appreciated. One frequently observes children going about with open mouths, broad and flattened noses, and dull, vacant expressions, all indicating the obstruction to nasal breathing usually due to lymphoid hypertrophy. The oft-repeated phrase, "They will outgrow it," accounts for many cases of chronic coughs and permanent deafness, as well as impaired mental and physical vigor. These children do not outgrow the affection. The cough which often accompanies this condition is a persistent symptom, increasing in damp weather and lessening in warm, dry weather. The treatment is largely surgical. It is true that in recent cases, if mild, marked improvement follows spraying of the nose and nasopharynx with iodin, grains ii to ℥ i of water, and the internal administration of syrupus ferri iodid; but in most cases a permanent cure is not possible without more radical treatment. Ablation of the growths and the application of the galvanocautery are the only surgical methods which commend themselves to a surgeon. The galvanocautery is the more tedious method, usually requiring more than one sitting, and each application is followed by as much or even more reaction than excision of the growths. It seems to the writer that cauterization should be employed only when some special indication exists. The removal of the growths by the post-nasal cutting forceps or the curette is a very satisfactory procedure. The pain and annoyance following the operation are usually slight, and the disappearance of the symptoms is very gratifying, both to patient and operator. A general anesthetic is necessary in very young or nervous patients, but in older children cocain anesthesia is usually sufficient. The use of a general anesthetic adds danger to the operation, partly because the patient is unable to freely expel the blood from the throat. The danger from this cause is lessened by careful administration of the anesthetic and maintenance of the head on a level lower than the body.

There are many morbid conditions of the pharynx capable of giving rise to cough. All of the acute and chronic diseases of the mucous membrane of this region may be accompanied by this symptom in greater or less degree. The accumulation of mucus in the pharynx will often excite a reflex cough, which is relieved by the removal of the offending substance.

Hypertrophy of one or both tonsils is a frequent source of cough. There does not seem to be any special relation between the severity of the latter and the size of the former. Some patients having large tonsils have little or no cough, while others, in whom the hypertrophy is moderate, have a very persistent cough which disappears only when the hypertrophy is removed. An accumulation of a white, cheesy matter in the crypts of the tonsils will often keep up an irritating cough, which will promptly disappear upon the removal of the accumulation with a curette. Elongation of the uvula is a common cause of an irritable, hacking or a spasmodic cough. Many cases of months' or even years' duration, in which a diagnosis of consumption has been made, have been cured within a few days by amputating the tip of the uvula. One ought to be careful not to remove too much of this organ. It is usually not necessary to remove any of the muscular substance, but simply the relaxed, edematous tip.

Cough is frequently a result of hypertrophy of the follicles in the posterior wall of the pharynx. The writer has found the best treatment for this condition to consist in the application to each follicle of the galvanocautery point. More than three or four applications should not be made at one sitting, as there is sometimes considerable reaction. Cleansing applications should also be employed to remove the accumulations of mucous, and if there be atrophy of the membrane between the follicles, stimulating applications are indicated.

Hypertrophy of the lymphoid tissue at the base of the tongue may be responsible for an irritating cough. One can easily detect this condition with a laryngeal mirror, and an application of the cautery will bring speedy relief, or if the follicles are numerous, or very much enlarged, they may be curetted or removed with a cutting-forceps.

Hypertrophy of the lymphoid tissue in the lateral wall of the pharynx frequently causes a hacking cough. This chronic lateral hypertrophy is often overlooked as a cause of this symptom. Objectively, the posterior wall of the pharynx may be found to be normal, or the seat of follicular hypertrophy, and along the lateral wall of the pharynx, behind the posterior pillar of the fauces and parallel with it, may often be seen an intensely congested and thickened ridge. This ridge of hypertrophied tissue is sometimes nearly covered by the posterior pillar, and may be best observed when the patient phonates or gags. Schmidt calls attention to the frequency of this condition in singers. The treatment is very satisfactory. Mild cases rapidly improve by applying nitrate of silver, grains xv to ℥ i of water. Two or three applications are sufficient to relieve the cough in some cases; but more permanent benefit may be obtained by applying the galvanocautery.

There are, no doubt, many other lesions of the nose and throat which may give rise to cough, but those mentioned by the writer have, in his experience, been frequently overlooked.

The following brief histories may be of interest in this connection:

CASE I.—Female, aged seventeen years. The symptoms were: cough for one year, with no expectoration, pharynx dry, frontal headache. Examination of the chest was negative. The pharynx showed commencing atrophy of the posterior wall, with injection of the vessels and accumulation of mucus. Treatment consisted of applications of ichthyol, grains x to ℥ i of water, after thoroughly cleansing the mucous membrane. Under this treatment the cough entirely disappeared.

CASE II.—Male, aged twenty-one years. He complained of a sore, irritable throat which was worse in the morning. Cough for four years, with some mucus expectoration, occasionally tinged with blood. There was also nocturnal nasal obstruction. Examination: Chest, negative; nose, hypertrophy of both inferior turbinates; pharynx, very much congested and irritable; uvula, elongated and relaxed. Treatment: Astringent sprays were used in the pharynx for about a week with some improvement. The uvula was then amputated, with entire relief of the cough.

CASE III.—Male, aged twenty-nine years. He had had trouble with his throat for over five years, causing him to cough and to hawk up mucus, and he complained of a sensation as of a lump in his throat. Examination revealed moderate hypertrophy of the anterior portions of both inferior turbinates; the vessels of the posterior wall of the pharynx were injected, with commencing atrophy of the mucous membrane, and an accumulation of mucus; the larynx was somewhat congested, though otherwise normal. On examining the lymphoid tissue at the base of the tongue, one follicle was found to be very much enlarged. After cleansing the mucous membrane of the nose and throat, an application of a fifty-per-cent. solution of oleum picis in albolene was made. The galvanocautery was applied to the enlarged follicle at the base of the tongue, with the result that the symptoms entirely disappeared. About three weeks later the cough and sensations as of a lump in the throat returned, with the addition of a constant, bitter, metallic taste in the mouth. I found on examination that the same follicle was again enlarged, and its thorough cauterization resulted in permanent relief of the symptoms, but there remained an ulcer at the site of the cauterization which would not heal under local applications. I suspected specific trouble, and on carefully questioning the patient, found that he had had syphilis many years before. Ten grains of iodid of potash was administered three times daily, and in about a week the ulcer was entirely healed.

CASE IV.—Female, aged thirty-five years. She complained of a dry, hacking cough which she had had two months, so severe at night as to prevent sleep. She also had a sensation as of a foreign body in the throat. She was in good health up to the time of the commencement of the cough; since then her appetite had been poor and her nutrition had suffered. Examination of the nose was negative. The pharanyx was congested, there being lymphoid hypertrophy behind and parallel to the posterior pillar. There were several good-sized hypertrophied follicles in the posterior wall, with commencing atrophy between them. The upper portion of the larynx was congested. The tongue was covered with a white coating. After cleansing the pharynx, a solution of nitrate of silver was applied, grains x to ℥i of water. Codein, ¼-grain, was administered for two nights to control the cough. The galvanocautery point was applied to the hypertrophied follicles, several sittings being necessary. The cough had almost ceased in less than a week, and in another week and a half she was entirely free from it. She was obliged to leave town before all the follicles had disappeared, but when last seen the cough had not returned.

CASE V.—Male, aged twenty-six years. In regard to asthma or nervous diseases the family history was negative. He had had asthma since an attack of whooping-cough which occurred when he was a child. Three years before coming under observation he gave up farming because of dyspnea and general ill-health. He had noticed marked nasal obstruction in the right side for several months. He had asthma all this time, but it was worse during wet weather. Cough, which was most annoying during the early morning hours, pain in the left side of the chest, and constant dyspnea were the principal symptoms noted. Examination of the lungs showed the sibilant breathing, prolonged expiration, and an abundance of coarse mucous râles. The right side of the nose was obstructed by polypi. The use of drugs gave but temporary relief. The polypi were removed with a snare, and their bases cauterized. The patient experienced prompt relief, and when last seen he was much better than he had been at any time for many years.

A CASE OF INFANTILE SCURVY, WITH COMMENTS ON INFANT-FOODS AND FEEDING.[1]

BY ARTHUR M. JACOBUS, M.D.,
OF NEW YORK.

THE health and family history of the parents of the girl baby whose case is herein reported has always been good, excepting that from overwork in looking after a large household, the mother's physical condition was not up to par during the early part of the pregnancy which resulted in the birth of the patient. The mother had previously given birth to four children, two girls and two boys, all of whom have enjoyed excellent health, excepting that the fourth child, a boy, was inclined to mild attacks of eczema during the latter part of the nursing period, when he was also given artificial food. The parents and all of the children are of the auburn-blonde type. Three months before the fifth baby was born, the one whose case is here reported, the mother and family, who had been under my care at different times during three or more years, removed to a mountainous country home, having an elevation of nearly 1400 feet above sea-level, with most healthful surroundings, and it was at this place that the baby was reared.

The patient was born July 13, 1896, the labor being normal in every respect. The child, a small one, was not weighed at birth. The family history has been purposely mentioned to show that it could not have been an element in the case. The mother's version of the baby's illness is so significant and excellent that it is given in full, as follows:

"I nursed the baby, and apparently had enough milk for her, but she did not seem to grow as rapidly as she ought, and when I spoke to the doctor about it, he said he thought the quality of my milk was probably not good and I had better wean her. I was very well at this time, had a good appetite, but was growing quite stout. I weighed 146 pounds, and my usual weight is only about 127 to 130. I thought that what I ate seemed to make flesh rather than produce milk, and the doctor seemed to think so too. I never gave her any other food as long as she had breast-milk, and after she was weaned, which was when she was just five months old, she had —— [mentioning the name of a well-known baby-food] and nothing else, until I went to New York in the spring, when I told you [Dr. Jacobus] about her wetting so much, and you advised me to try more solid food, and also to give two or three teaspoonfuls of cream with each feeding, which I did. We could not make her eat anything like eggs, or solid food in any form. . . . I do not remember the weight at different ages, but I know that just before we took her away in the middle of September, 1897, when fourteen months old, she weighed 14¼ pounds. She has never been sick until the present illness, excepting a slight attack of measles, which she had at the same time she was cutting her first teeth, which she did when she was seven months of age. Her food seemed to agree with her, was well digested, and her bowels were in good condition. She never had more than two or three loose passages at a time, and those usually just preceding the appearance of a tooth. The doctor here never said anything about her, although I told him that she did not seem to grow like the others. He only said, 'She's taking it easy.' She had a faint color, and her lips were red, until September 15, 1897, when she suddenly seemed to droop, refused her food (the proprietary food) and in a week's time became so emaciated that to handle her caused pain, and so we carried her on a pillow.

"During this time she passed very little water, sometimes going as long as seven hours without doing so. She had a little fever, but not much. During this week she cut four teeth, the anterior molars, making twelve between the ages of seven and four-

[1] Read before the Northwestern Medical and Surgical Society of New York, November 17, 1897.

teen months, and her bowels became distended, the stools being curdy and green. The doctor here attributed this to the fact that we had given her two doses of cod-liver oil, but they continued in the same condition until after we had changed her food as you directed when we consulted you some time later. In the middle of September the doctor here advised a change of air to the seashore, in order to save her life, which seemed rapidly passing away. We took her to Seabright, N. J., after calling at your office and finding you out of the city, and the doctor there said at once that her trouble was scurvy, and ordered orange juice for her, also meat juice. But he told us to let it get cold and take the grease off and then heat it. This she took for a few days, but soon got so she could not keep it down. She did not begin to gain until after we saw you in New York two weeks later and changed her food. That was the 27th of September, and she still weighed only 14¼ pounds. We brought her home October 1st, and the next day noticed a slight swelling of her hands and feet. It did not seem to extend further than her wrists and ankles, was at its worst on October 4th, began to decrease by that time, and had entirely disappeared in about a week. Her urine was examined at that time, and found to be normal. During the week her color began to improve, although so slightly as to be scarcely perceptible. She gained a pound that week, a quarter the next, and seven ounces last week. She now (October 25, 1897) weighs sixteen pounds, and is as rosy a baby as you would wish to see, but is still very thin in the legs and arms. The skin on her limbs is dry and scaly. We have been rubbing her with cod-liver oil, and I hope it will soon be better. Lately we have been giving her oatmeal in her milk and cream mixture, in place of the barley, and her constipation seems better.

"I met the doctor on the street this morning, and he asked me if I was still giving the baby meat and orange juice, and advised me to discontinue it, saying the necessity for it was past. I have not done so, nor do I intend to unless by your advice. A week previous he had also told me to skim the milk and not give the baby any cream, as it was too rich for her. Baby never had any rash or blood spots."

This ends the mother's intelligent history, as she observed the baby's illness, and, to my mind, depicts a typical case of scurvy. I have given it in full for the purpose of showing that her physician, a skilled surgeon with a large general practice, had evidently failed to make a diagnosis of the real condition, or to suggest the proper remedy—a change of food. When I saw the baby for the first time it was in New York on September 27th last, on its return from Seabright, N. J. The child lay on a pillow, was profoundly emaciated, with lips and face bloodless, pulse so weak and rapid that it was almost imperceptible, and apparently the baby had but a few hours to live. I had, a short time previously, on hearing the mother's story, made a diagnosis of scurvy without seeing the baby, and then the mother told me the Seabright doctor had said the same thing, but had not changed the food, excepting to order meat and orange juice. The mother said that the child's gums, which were a dark red and swollen, were somewhat better, but otherwise it had continued to fail, had a slight cough and fever, and had not improved by the trip to the seashore. The legs at this time were puffy, and movements seemed to cause pain, but there was no real edema. The baby, then fourteen and a half months old, had been fed almost wholly on the proprietary food since weaning, at the age of five months, and though the mother was not going home for several days, where the best milk from her own select herd of cows could be obtained, she was directed to stop entirely the food referred to and to give the following instead:

Robinson's prepared barley, well cooked with water, and as thick as rich milk, and the best cow's milk that she could obtain in the city, *unsterilized* or raw, in equal parts, with two teaspoonfuls of pure cream, two teaspoonfuls of lime water, and one-half to one teaspoonful of the best granulated sugar at each feeding. It was directed that the child be fed about once in two to three hours, depending upon the quantity she could take and retain at each feeding. At first she could only take about three ounces at a feeding, but by the end of the second week she took as much as five or six ounces, and later, eight to ten ounces. After the second week the proportion of milk was increased to two-thirds, and barley or oatmeal water and the rest of the mixture together making one-third. From the first she was also given the juice of two medium-sized choice sweet oranges each day in teaspoonful doses, with sugar, and as much water then and between feedings as she desired. The mother was told that she could give the baby the diluted sweetened juice of one lemon each day if at any time unable to obtain good oranges. The child was also given beef juice prepared as follows: I had heard from some teacher that beef juice should never be allowed to become cold from the preparation to the feeding, otherwise there would be a chemic change injurious to the juice, so that the mother was told to take a small piece of "top sirloin," sear it quickly, first on one and then on the other side, and then to broil it over a bed of live coals until the juice began to run, when she was to score it with a hot knife, squeeze it with a hot lemon-squeezer into a hot saucer, and add a pinch of salt and serve with a hot spoon as it cooled down sufficiently to be fed to the baby without burning its mouth. The baby was fed from two to four teaspoonfuls of beef juice freshly prepared in this manner twice each day. This was the entire treatment. No medicine whatever was given either for the cough, fever, profound anemia, indigestion, constipation, edema, scanty urine, sore gums, or anything else. The result has been sure and rapid, as might have been expected by any one with previous experience with this dread and often unrecognized condition. I should add that at first, as usual in scurvy, the baby rebelled against taking the beef juice, but subsequently it was taken with relish. It should also be recalled that though the physician in Seabright recognized the condition and

ordered beef and orange juice, which was given, the baby continued to fail, and it was not until the food was changed that she began to improve. A recent report is that the baby is steadily gaining in appearance, weight, and strength, and in fact is apparently well in every respect.[1]

Had this baby been under my immediate care, as were the other children, the mother would never have continued to give the proprietary food so long as she did, with my consent, but as the mixture had apparently agreed with the next older child who, however, was also given other food, she continued it with this one, especially as her local physician had made no comment that the child's illness was due to improper food.

Scurvy is generally considered to be a disease of malnutrition, and customarily attributed to a lack of vegetables, but the latter cause is certainly very doubtful in the case of children. Dr. W. Gilman Thompson, in his work on "Dietetics," says that it is a disease due to omission and not to consumption of certain foods, and that it depends rather upon the quality than quantity of food. He also says, in opposition to the theory that the want of fresh vegetables acts as a cause of scurvy in man, that the fact is stated by Lieutenant Greely that among the Danish Eskimos, who have a population of ten thousand, not a pound of vegetables, nor a dozen pounds of bread per man are eaten annually, and yet they are practically free from this disease, and the same statement is made in regard to the most Northern tribes of Eskimos of pure blood, who were studied by Lieutenant Peary, and also in regard to the natives of the Alaskan Archipelago and some tribes of North American Indians who do not include either vegetable or bread in their food. Scurvy in infants is said to occur as early as the fourth month, but most frequently between the ages of nine and eighteen months, or about the time the mother's milk begins to fail and artificial foods are resorted to. In looking over the literature of scurvy, it is found that the disease in children, in nearly every instance, is reported to have occurred where the infants had been fed almost exclusively on some one of the following foods: Proprietary preserved foods, condensed milk, peptonized milk, sterilized milk, and even barley water is mentioned as a cause. Northrup, according to Thompson, does not state it any too strongly when he says: "It is a significant fact that the country which furnishes most of the literature of scorbutus in children is the same which is posted from end to end with advertisements of proprietary foods." It may be inferred, therefore, that preserved, cooked, or sterilized foods lack something essential to the infant's healthful development. The remedy, then, lies in raw milk or simple mixed foods.

In the Addenda of Dr. A. Jacobi's valuable book on "The Therapeutics of Infancy and Childhood" may be found a number of lines which, perhaps unintentionally on his part, confirm the inferences just made in regard to the causes of scurvy. He says, for instance, that "*sterilized* milk, if the only nutriment, as in many instances it will be found to have been, must be combined with cereal decoctions, and meat broths should be added as a regular food." And yet, though he lauds sterilized and pasteurized cow's milk, chiefly in intestinal disorders, he admits, "There can scarcely be a doubt that if raw milk could always be had unadulterated, fresh, and untainted, it would not require boiling; it would even contraindicate it, for high temperatures at once destroy the bacteria whose action is desirable for normal digestion." He admits also that "boiling or sterilization is not a safe protection under all circumstances," that it takes hours of sterilization to destroy certain bacteria, and that such protracted sterilization, besides being far from certain in its effects, is a clumsy procedure, and one not calculated to benefit the milk, and that it has been claimed to have been no unmixed boon because of its changing the chemic constitution of milk. Again Jacobi states, "But what I have said a hundred times is still true, and borne out by facts, *viz.*, that no matter how beneficial boiling, sterilization, or Pasteurization may be, it cannot transform cow's milk into woman's milk, and that it is a mistake to believe that the former, by mere sterilization, is a full substitute for the latter. Further, that the substitution of cow's milk or of sterilized cow's milk for woman's milk, as the *exclusive infant* food, is a mistake. Also that experience teaches that digestive disorders, such as constipation or diarrhea, and constitutional derangements, such as rachitis, are frequently produced by its persistent use, and it appears to be more than an occasional (at least cooperative) cause of scurvy."

If all this is true, and certainly Dr. Jacobi ought to know whereof he speaks, what is the use of going to all the trouble to sterilize milk, thereby injuring its nutritious and healthful qualities, and in the end run the risk of causing infantile scurvy, rickets, and kindred disorders? Why not absolutely discard all artificial proprietary foods, sterilized and peptonized milk, excepting the latter two as a temporary diet in acute intestinal disorders, and in the absence of *good* human milk give pure, fresh, filtered cow's milk properly modified and diluted to conform to human milk, and which now, owing to the rigid inspection of dairies can be readily obtained in most cities?

[1] Examination of the baby, December 26, 1897, showed her to be in excellent health.

Jacobi,[1] Soxhlet, Caillé, Seibert, and others, deserve great credit for their work in calling attention to the deleterious influences and dangers of impure milk, and in advocating so thoroughly sterilization and the best methods of performing the same, but excepting as a temporary diet in intestinal disorders, or where it is absolutely impossible to obtain pure milk, I believe time will show that it, like proprietary foods, condensed milk, etc., when relied upon as the main diet, will prove detrimental to the health of infants, and particularly that it is a causative factor in scurvy.

In my opinion, scurvy is mainly a constitutional disorder due to slow or chronic starvation, resulting in profound anemia and other morbid processes in the animal economy, and due to a lack of foods in proper variety, suitable to the digestive powers and requirements of the individual. In other words, that preserved or proprietary foods and condensed and sterilized milk, lack certain natural chemic acids and substances necessary to the health of a child, and which cooking and sterilization seems to destroy and which we are not yet in a position to isolate.

Seibert has shown in a series of experiments that sterilization as usually performed, and even by himself, does not eliminate all bacteria, or at least, that bacteria develop in previously unfiltered sterilized milk much quicker than in milk which has been filtered before sterilization according to the method described by him. I believe that in filtered milk lies the solution of the difficulty. That is, first, in the absence of good human milk obtain the purest rich cow's milk which can be obtained; carefully filter it, as directed by Seibert, dilute it freely, and modify it, as described by Jacobi, Rotch, and others, by the addition of water, cane-sugar, and barley, rice, or oatmeal, and lime-water, according to the necessities of each particular case, and a food is obtained which will be perfectly satisfactory. In addition, after the age of six months, there being no special contraindication, and certainly, if the infant is failing on a restricted patent or milk diet, other simple foods, such as baked potatoes (which Watson, in his celebrated work on "Practice," proved over fifty years ago is a specific equal to lemon juice in scurvy), beef juice, fresh fruit juices, vegetables, crackers, etc., should be carefully given as extra diet.

In my experience, the infants most affected with malnutrition, anemia, scurvy, etc., are those of the well-to-do classes who can afford to purchase artificial foods, and who give them because some friend's child apparently did well under such circumstances. On the other hand, the children of the tenement population, as I recall them, as a rule suffer less from these disorders because they sit at the table and are fed on everything that the parents eat, such as tomatoes, potatoes, fruit, meat, crusts of bread, rice, etc., and even beer. Unfortunately, in hot weather, owing to the heat and foul air of the crowded tenement-houses and the exposed and infected groceryman's milk and other infected foods, the infants suffer and frequently die of acute intestinal disorders.

In selecting cow's milk as a portion of the diet, we should be careful to exclude all milk from cows fed on beer grains, as the latter increases the amount of water, acids, etc., in the milk and diminishes the cream. The one cow's milk also, should not necessarily be used, unless its quality has been determined by analysis. I recall a case in which an infant was suffering from dyspepsia and malnutrition following the use of very poor milk from one cow; I suggested an investigation, which resulted, as I expected, in finding that the one cow from which the milk was derived was housed in a filthy stable, and was fed on beer grains and sour, decaying garbage and swill. A change of milk at once effected a cure. We must also, when possible, exclude milk when the morning and evening milkings are mixed together. Milk of different ages, like wine, should be kept separate.

Owing to the length of this paper, but little will be said on the modification of cows' milk to make it correspond as nearly as may be to average good human milk. In the writings of authorities already alluded to and, in fact, in any of the recent well-known text-books on diseases of children, will be found a full discussion of this subject, and I have nothing new to report. It is only necessary to remember that in the "artificial feeding of infants no routine mixture will in all cases prove successful," and that "slight changes in the three elements of milk of which we have the most accurate knowledge, namely, fat, sugar, and albuminoids, are of real practical value in managing the digestion and nutrition of the infant. Cows' milk must be well diluted with water, containing by preference a cereal; in order to diminish the excess of proteids or albuminoids, and in doing this we must make up the loss, in proportion, of the fats and sugars." Dr. Jacobi is a great believer in high or extreme dilution of milk with water, and since I have adopted his advice in that respect my success in feeding cows' milk to children has correspondingly increased. Infants are often sick and famished for the want of water, even during the nursing period. Lime-water or bicarbonate of soda must, of course, be added to cows' milk to diminish the occasional excess of natural acidity, and for

[1] Jacobi claims to have practised sterilization of milk forty years, and to have taught it thirty-five years.

its effects in breaking up the casein into small, easily digestible flakes. Holt advises it in the proportion of one part of lime-water to twenty of milk, or one grain of soda to one ounce of milk. Finally, to again quote from Jacobi, who says: "I am pleased to state that Auerbach agrees with me on another subject. The sugar he adds to the milk-food of infants is not milk-sugar, but cane-sugar, of which he gives twenty grams daily, and also, according to my old teaching, more during constipation. He undoubtedly prefers cane-sugar for the reasons which guided me in my recommendations, though it is true that milk-sugar is being stripped of its dangers in the same degree as boiling, sterilization, or Pasteurization is carefully practised." I will add that since adopting the foregoing suggestion in regard to cane-sugar, it, too, like the extreme dilution previously referred to, has given me the happiest results.

Summary.—The causes of scurvy are many—chiefly poor human or cows' milk, improperly modified good cows' milk, proprietary foods, condensed and sterilized milk, the three latter being relatively unsuitable in the order named, and, finally, a lack of cereals and raw foods, meat, fruit juices, etc., in variety and quantity suitable to the age of the infant.

The treatment, fortunately, is generally simple. First, we must absolutely prohibit the use of patent and proprietary foods, and next supply a food, in the absence of good mother's milk, such as has been suggested. As Thompson says, and Osler, too, in nearly the same words, "the treatment of scurvy in children consists first in throwing away all proprietary foods, condensed milk, etc.," and sterilized milk also, it might be added; and then, if the disease has not progressed too far, improvement and cure rapidly follow change to a normal diet, including expressed beef juice, and a little fresh orange, lemon, or peach juice.

TUBERCULOSIS OF THE TONSIL.[1]

BY SEYMOUR OPPENHEIMER, M.D.,
OF NEW YORK;
ATTENDING LARYNGOLOGIST TO THE OUT-DOOR DEPARTMENT OF BELLEVUE HOSPITAL; ATTENDING LARYNGOLOGIST AND OTOLOGIST TO YORKVILLE HOSPITAL AND DISPENSARY; SENIOR ASSISTANT TO THE CHAIR OF LARYNGOLOGY, UNIVERSITY MEDICAL COLLEGE.

IN the study of tuberculosis of the tonsil it becomes necessary to divide the disease into two classes, the primary and the secondary. The primary form is very rare, but few cases having been reported from time to time, and even the authenticity of these admits of considerable doubt. Störck submitted twenty tonsils, removed *post-mortem*, to minute microscopic examination, and found two presenting tuberculous changes. That tubercle bacilli are present in a considerable proportion of apparently normal tonsils and especially in the hypertrophic form of tonsillitis, has been demonstrated by several Continental pathologists and laryngologists, experimental inoculations being performed upon guinea-pigs and rabbits. In all these experiments the tonsils were removed from the ordinary class of patients seen in a throat clinic, and though hypertrophy was present in all, no evidence of either local or general tuberculosis could be detected. Shenker and Kruchmann, in an extensive consideration of the pathology of this disease, establish the causal relation between primary infection of the tonsillar tissues with the tubercle bacilli and tuberculosis of the cervical lymph-glands.

Primary infection may occur from the use of contaminated instruments (and especially the laryngoscope, which is very difficult to keep surgically clean), from the inhalation of air containing the tubercle bacilli, or from the ingestion of tuberculous food. In dispensary practice, where the number of patients treated within a limited space of time is very large, it is almost marvelous that more cases of tuberculous infection do not occur. The necessary instruments are often not properly cleansed previous to use with each patient, frequently being merely wiped off with a towel or napkin which has sufficed in perhaps ten or twenty similar instances. There is no doubt that tubercle bacilli are frequently transmitted from one patient to another in this way, but on account of the natural resistance of the parts, infection does not result. The dust in the majority of dwellings, especially those occupied by the poorer classes, contains a considerable number of tubercle bacilli, and, as the subjects of the ordinary hyperplasia of the tonsil sleep and usually live with the mouth open, using the nose but seldom as the primary respiratory organ, it is very apparent why the bacilli should be found in the tonsillar crypts. It is hardly necessary to say anything in regard to the ingestion of tuberculous food as a cause of local infection; for, with the exception of milk, the majority of food-stuffs are free from this contagion.

On examination of the tonsils suspected to be the seat of primary tuberculosis, we will not be able to discover anything indicating the character of the affection; they may appear normal, or, as is usually the case, hypertrophied. If a small piece of tonsillar tissue be removed for diagnostic purposes and subjected to staining with hemotoxylin-eosin, the lymph-cells will be colored bluish-red, while the tubercle bacilli will assume the peculiar shade known as eosin-red. Occasionally the diagnosis must be

[1] Read at the Fourteenth Annual Meeting of the New York State Medical Association, October 13, 1897.

based upon this staining method alone, but usually giant-cells and tubercles, more rarely caseation, may be found. Primary tuberculosis, although rare, is probably present more frequently than we suspect, and possibly many cases of pulmonary tuberculosis find their origin in infection through the tonsils.

When the tonsil is the seat of a tuberculous process, distinctly localized in this gland, one of two results follow: either the disease remains local, not affecting the patient in any way and only discovered after removing the tonsil for other causes, or pulmonary tuberculosis develops from infection through the lymphatic system. The treatment of this primary form is very simple, and, if the disease is localized in the tonsil, is absolutely curable by removing the infected tissues. Tuberculosis of the tonsils consecutive to the pulmonary form is of quite frequent occurrence. If you consider, according to reliable statistics, that about every seventh human being dies from pulmonary tuberculosis, while *post-mortem* records of various large hospitals prove that certainly not less than eighteen per cent. of all patients dying from tuberculosis of the lungs have some pharyngeal or laryngeal complication, you will see that, broadly speaking, every thirty-fifth patient dying in the practice of a general practitioner, is afflicted with the ravaging disease under consideration. Strassman found the tonsil involved in thirteen out of twenty-one fatal cases of tuberculosis.

On examination of fauces, the seat of the tuberculous changes, we find the tonsils hypertrophied with no distinctive lesions, or, ulceration may be present on the tonsil, soft palate, or pharynx. The ulcers on the external surface of the tonsil are uneven or ovoid in shape, pale in color at their circumference, but having a red, slightly granular base. Anemia of the surrounding mucous membrane is usually well marked. The ulceration is very superficial, extending laterally rather than deeply, the surface being covered with a dirty, yellowish-gray secretion. The soft palate and uvula are usually thickened with a semi-solid infiltration peculiar to this disease, and known as submucous infiltration in contradistinction to deep infiltration as observed in syphilis. Frequently the tissues are thinned from atrophy or lack of nutrition and the epithelium covering the tonsil is thinned in patches from submucous swelling or from the pressure exerted by a distended crypt. The mucous membrane of the pharyngeal cavity and soft palate is markedly anemic, often in strange contrast to the apparently normal complexion of the patient. The anemia shows itself in the form of either a general pallor of the soft palate and pharynx, or in the form of what at first sight appears to be congestion, but which, on close inspection, is seen to be an injection of the capillary vessels, so marked that even the smallest branches may be distinguished on the intensely anemic mucous membrane. In the neighborhood of the ulcers are small elevations or tubercles, varying in color from deep red to yellow. Schnitzler made the diagnosis of tuberculosis, in one case even before there were signs of the disease in the lungs, by excising one of these small granulomata and finding tubercle bacilli present.

The local symptoms are principally pain and dysphagia. The pain is intense, but is usually confined to the diseased region. Frequently the suffering is so severe that it is impossible for the patient to swallow without the use of an anodyne, and in this connection it is interesting to note that liquids are generally more badly borne than solids or semi-solids. The pain is especially severe if the posterior pharyngeal wall and larynx is involved. The extreme dysphagia will often necessitate the use of nutrient enemata, especially as the fatal termination draws near. The voice, as a rule, is not impaired unless the larynx is involved; but if the disease is far advanced, and especially if the tonsils are hypertrophied or ulcerated, the voice is changed in quality, and its use is extremely painful. The mere swallowing of the saliva causes excruciating pain, and the patient goes without food to avoid the agony accompanying the act of swallowing. Taste and smell may both be impaired, or even abolished, and the breath has a peculiar, offensive odor, which is more or less characteristic of the disease in this locality.

The diagnosis of tuberculosis of the tonsil in the majority of cases may readily be made, especially if there is marked concomitant pulmonary changes. The characteristic ulcers on the tonsils and soft palate, the intense pain, and the emaciation with hectic fever, are all readily recognized. A study of the temperature affords considerable evidence in favor of the disease, if the tonsillar lesions are not well marked.

There are three diseases to some extent resembling tonsillar tuberculosis: *viz.:* lupus, syphilis, and cancer. Lupus of the tonsils and pharynx is very rare, and the coexistence of a cutaneous lesion will assist in clearing the case. Cancer may usually be distinguished by the ulcerations, which are deep and angry-looking; its course is very rapid, and the cachexia is generally present. In the early stages of carcinoma, before ulceration is present, resource to the microscope and the finding of the characteristic epithelial elements readily solves the question of diagnosis.

As to syphilis, its differential diagnosis may occasionally present greater difficulties, the more so as

the possibility of a double infection being present in one and the same patient must be borne in mind; the tonsillar lesion may be syphilitic, while the pulmonary is tuberculous. Resort to the therapeutic test with mercury and iodid of potassium in sufficient dosage will assist in establishing the diagnosis. In the more ordinary cases, however, tuberculous infections may be distinguished by the pallor of the affected parts, the syphilitic lesions being more of a decidedly inflammatory character. The development of the tuberculous ulcer is slow, that of the syphilitic rapid.

The general diagnostic features of syphilis, the absence of fever, the history of a primary sore, and the post-cervical glandular enlargements are not present in tuberculous affections. The characteristic pathologic changes in tuberculosis of the tonsil are not different in any respect from those seen in other portions of the body, the locality of the disease alone giving rise to its definite local symptomatology. Before the ulcers form tubercle must be present; these may occur as part of the morbid changes of other diseases, for example, syphilis; but the tubercle of tuberculosis is characteristic of the affection, and occurs in no other disease. Briefly, it may be described as consisting of an enlargement of connective tissue, translucent, grayish in color, and about the size of a millet-seed. The cellular elements are lymphoid and round cells, varying in size. The nuclei are generally small and homogeneous. Between the cells are found fibrous tissue, which is not very vascular. The vessels are never newly formed, but have existed in the tonsillar tissue before the development of the tubercle, the latter growing around them. The blood-supply is at all times very deficient. The nodules may be isolated or joined together in a mass from inflammatory changes, imperfect granulation tissue resulting. As the nodule grows older caseation begins in the center, the degenerating process progressing until the nodule is a mass of granular *débris*.

The prognosis is, as a rule, very unfavorable. If the tonsil alone is affected, removal, or prompt and radical medication, offers some hope, but if ulceration is present, and the larynx and pharynx are involved, little can be accomplished, except such palliative measures as will prolong life and make the patient as comfortable as possible.

Lenox Brown outlines the treatment as follows: "Counteract the general tuberculous tendencies; give as much functional rest to the diseased parts as possible; relieve the pain in swallowing; administer suitable nourishment, and attempt to heal the ulceration."

The constitutional treatment must always be enforced, as success cannot be hoped for unless strict attention is paid to the condition of the general health. The administration of cod-liver oil, the hypophosphites, nutritive tonics, proper feeding, etc., should be carried out as if the case were pulmonary in character. Functional rest of the parts is extremely important, as every time the patient swallows or talks the movements of the muscles concerned in phonation or deglutition keep up the irritation. If the ulcerations are extensive, speaking must be prohibited, and food administered by means of the esophageal or rectal tube. Relief of the pain in swallowing will necessitate a careful consideration of the food. The nutriment should be of a semi-solid consistency, such as jelly, eggs, poached, soft, or boiled, scraped meat juice, etc. Heat is usually very painful, while cold is grateful; so ice may be given in small pieces.

Of the drugs used to relieve the pain, cocain is undoubtedly the best. I have lately been employing a pastil composed of morphin, cocain, and antipyrin, which the patient allows to dissolve in the mouth. The treatment of the ulcers is very unsatisfactory. In my experience but one method of treatment has proved to be at all efficacious, *viz.*: that of curetting the ulcer with a sharp spoon, and then cauterizing with lactic acid. We owe the application of this drug to the therapeusis of tonsillar tuberculosis to Krause of Berlin. Moorhoff of Vienna had extolled its merits in the treatment of tuberculous disease of the joints, and Krause utilized the suggestion in the treatment of the same disease in the larynx. In the majority of cases this method gives the best results, cocain being used before the application of the acid. Of the internal remedies recommended at various times for the treatment of pulmonary tuberculosis I now, in most cases, employ but one, *viz.*: creosote in large doses. The use of this drug, combined with lactic-acid applications, has yielded the best results in my hands. In conclusion, quoting Semon, "I can only recommend you, as long as we have nothing better, to adopt this method of treatment, and I hope your endeavors may be crowned with successful results."

THE ANATOMY AND SURGERY OF THE MIDDLE MENINGEAL ARTERY.

By H. A. SIFTON, M.D.,
OF MILWAUKEE, WIS.;
PROFESSOR OF ANATOMY IN THE WISCONSIN COLLEGE OF PHYSICIANS AND SURGEONS.

In order to investigate the origin, relations, course, distribution, anastomoses, and size of the middle meningeal artery, sixty dissections were made upon thirty-four subjects. The origin was from the internal maxillary artery in fifty-seven of the sixty cases; in

one it was from the external carotid; in one from the internal carotid, and in one from the ophthalmic. The anomalies were all observed on the left side. The point of origin was very constant, always being between 11 and 13 mm. from the division of the external carotid; in five instances the division into branches occurred before the skull was entered. In the fourteen cases in which the artery was injected it was found to anastomose freely with other meningeal arteries and with the corresponding artery of the opposite side. Its size was noted in forty cases in which a plug of the injecting material was squeezed out and measured, and the vessel was found to vary between 1 and 2 mm. in diameter. The anterior branch was from ¾ to 1 mm. in diameter, and the posterior branch less than 1 mm.

The location of the artery in question is not between the dura mater and the bone, but in the substance of the dura mater, surrounded by a fibrous process of that membrane. A rupture may occur without a fracture of the skull; and in case of injury the rupture of the artery may be some distance from the point of traumatism, or even on the opposite side of the head. The symptoms caused by a rupture of the artery are those resulting from the pressure of the extravasated blood. It has been estimated that the force exerted by an extravasation 10 mm. in diameter, with a tension of 10 mm. of mercury in the arteriole, is about three atmospheres, a pressure sufficient to destroy any portion of the brain.

The symptoms following rupture are as follows: An interval of consciousness after the injury, followed by coma with spastic movements, ending in paralysis. The condition of the pupils and the character of the pulse vary with the degree of pressure. The respirations are irregular; coma comes on slowly or rapidly, according to the rapidity with which the blood is poured out. The only rational treatment consists in an immediate opening in the skull, turning out of the clot, and arrest of the hemorrhage.

The following cases will serve to illustrate the symptoms and treatment:

CASE I.—John D., a farmer's boy, aged ten years, was sent to turn a horse loose in a pasture, the latter being about a quarter of a mile from his home, at 11 A.M. in the forenoon, and as he did not return to dinner, search was made for him. He was found near the house lying on the ground in an unconscious condition with blood oozing from a small cut over the left temple. A physician was sent for who diagnosed a fractured skull. On my arrival, about three hours after the accident, the boy was in an unconscious condition with slow pulse, cold extremities, and irregular breathing. He was so profoundly comatose that it was impossible to get any response from pinching.

The doctor stated that at the time he first saw him, two hours earlier, he responded to pinching on the left side, but gave no response on the right, although there was marked twitching of the right side of the face, shoulder, and arm. The wound of the left temple was 1½ inches posterior to the external angular process, and one inch above the zygoma. It was about an inch long, and had evidently been inflicted by the cork of a horseshoe, as the outline of the flat part of the shoe could be seen extending backward from the wound. On exploring the opening with the finger a fracture of the skull was found, although no marked depression could be detected.

The boy must have walked a quarter of a mile after being struck, as the horse was found in the pasture with the gate shut. This was conclusive evidence that he did not at once become unconscious, or if he did, he had recovered from the first blow for a sufficient time to allow him to walk the quarter of a mile. The unconscious condition had gradually grown more profound, progressively involving the various groups of muscles of the right side from the face downward, showing that the pressure was increasing and extending. A diagnosis of probable injury to the middle meningeal artery was made.

The external wound was enlarged by a curved incision which disclosed a slightly depressed area with a fissure extending backward. A trephine was applied, and a button of bone removed, including a part of the depression. On taking out the button of bone a dark clot was exposed. The opening was enlarged with the bone-forceps and the clot broken up and turned out. It was large, extending in every direction, and was an inch in thickness opposite the opening. As soon as the clot was broken up, free arterial hemorrhage occurred, which after much difficulty, owing to the depth of the wound and the limited size of the opening, was arrested by passing a ligature under the bleeding-point and tying. This controlled the hemorrhage, and we were able to clear out the clotted blood as far as it could be reached. The artery from which the hemorrhage came could then be distinctly seen pulsating on the surface of the dura mater directly beneath the opening. It was the anterior branch of the middle meningeal, and seemed to have been torn completely across. The dura mater was apparently not injured. The brain did not expand and fill up the space left by the clot, so the cavity was loosely packed and the wound closed. No anesthetic was used, the patient manifesting no sense of pain.

On removal of the clot the breathing immediately become regular and the patient's condition improved, but he did not become conscious until twenty-four hours had passed. He was markedly dull during the following three or four days, and manifested some twitching of the right side of the face, shoulder, and arm, which were partially paralyzed. He did not fully recover for five weeks.

The gauze was removed on the third day, the wound healing by first intention. One year after the injury the opening in the skull had closed, and he was in perfect health.

CASE II.—J. M., aged twelve years, a healthy boy, while plaguing an Italian fruit-vender was struck upon the head by a broomstick. He was apparently not much hurt. A few minutes later, feeling sick, he walked home, a distance of four blocks, telling his mother that the vender had struck him, and complained of headache. As there was nothing but a slight bruise to be seen she thought little of it, and had the boy lie down. About an hour later he was noticed to be breathing hard an attempt was made to rouse him, but was unsuccessful.

I found him in a partly comatose condition, with slow pulse, irregular breathing, cold extremities, and subnormal temperature. He was restless, throwing himself from side to side, muttering and crying out if touched. It was apparent that he could not use his right hand with as much freedom as the left. After a few minutes, he lost all control of the arm and leg. Both eyes were rotated outward, with the pupil of the left dilated and immobile. An examination of the head revealed a slight bruise over the left temple, extending from the external angular process backward, and showing as a faint swelling on the line where the stick had struck him. It was evident that he was suffering from cerebral pressure, and that it was gradually increasing and extending. A diagnosis was made of intercranial hemorrhage, probably from the left middle meningeal artery.

He was removed to a hospital and prepared as quickly as possible for an operation. All the pressure symptoms had markedly increased so that by this time he was in a profoundly comatose condition. A curved incision was made over the left temporal region, the center of which was 1½ inches posterior to the external angular process and 1¼ inches above the zygoma. On turning back the flap no evidence of any injury to the skull could be found.

As a trephine could not be obtained, I opened the skull without difficulty with a metacarpal saw, taking out a piece of bone about 1¼ inches square, the center of which was located at a point over the anterior branch of the middle meningeal artery. On removing the bone, which was easily accomplished as it was quite thin, a large clot of blood protruded through the opening. This was broken up and removed. There was considerable oozing which seemed to come from the lower angle of the opening. After chipping away considerable bone, and being still unable to locate the bleeding-point, the wound was loosely packed with gauze, which finally controlled the hemorrhage. On removal of the clot the brain immediately expanded so that the dura mater came well up to the opening in the skull, and the breathing at once became regular. All the symptoms improved, and at the end of four hours the patient regained consciousness, although there was still some loss of power over the right hand and leg which did not pass off for two or three days. The gauze was gradually withdrawn until by the fourth day it was entirely removed. At the end of ten days the wound had healed, and the boy left the hospital in apparent good health.

Two weeks later he returned showing a small opening at one end of the scar which was discharging a serous fluid. A probe disclosed roughened bone at the edge of the opening. As there were no symptoms an antiseptic dressing was applied. After five weeks, during which time there was a very scanty discharge, I was able to detect with the probe that a shell of bone had separated, and without much difficulty it was removed. The death of this piece of bone is of interest in showing how the stripping off of the dura mater may determine the life of the overlying bone which receives its nourishment from it. Especially is this so in the young subject in which the dura mater is much more firmly adherent to the bone than in the adult.

It is conceded that had the wound been aseptic the piece of bone would not have exfoliated, but would have acted as a bone chip. Had the nourishment of the bone not been impaired, Nature would have overcome the shortcomings in the technic of the operator, and the wound would have remained closed after it had once healed. After the removal of the dead bone, the wound at once closed. Six months later there was still a small opening in the skull through which the pulsation of the brain could be felt. At the end of a year this had disappeared, and no evidence of the large opening remained other than a slight roughening of the bone beneath the scar.

CLINICAL MEMORANDUM.

A PERSONAL EXPERIENCE IN RENAL SURGERY.

BY ROBERT F. WEIR, M.D.,
OF NEW YORK;
PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, AND SURGEON TO THE NEW YORK HOSPITAL;
WITH THE COLLABORATION OF
EDWARD M. FOOTE, M.D.,
OF NEW YORK;
SURGEON TO THE RANDALL'S ISLAND HOSPITALS.

THE kidney was long the undisputed domain of internal medicine, but little by little surgery disputed this territory until now the only affections of these organs which may be considered strictly "medical," are acute and chronic, bilateral, non-pyogenic inflammations, and even the former of these have lately been made the subject of surgical interference by Harrison of London. This rapid advance in the surgical treatment of diseases of the kidney has been brought about not only by the daring of aseptic surgery, but by the improved methods of establishing an exact diagnosis, and this latter result is very largely due to the introduction of the cystoscope and ureteral catheterization. With this improvement in diagnosis and a corresponding increase in knowledge of the course of diseases of the kidney, treatment of affections of the ureter itself came into being, and the "surgery of the ureter" now occupies a well-recognized place in our art. In publishing the succeeding cases, based upon a personal experience, brevity is of necessity observed, and only such comments as are of practical import are presented, with the addition of such condensed

formation as bears directly upon the points developed by the histories. For convenience, rather than for pathologic or surgical reasons, all the cases in which operation was performed have been arranged in the following order:

TABLE I.

No.	Diseases.	Number of cases.
1	Nephralgia	5
2	Movable kidney	5
3	Renal calculus	7
4	Renal abscess	4
5	Hydronephrosis	3
6	Renal tuberculosis	9
7	Cysts of kidney	2
8	Neoplasms of kidney	3
	Total	38

Or stated differently the following operations were performed:

TABLE II.

Operations.	Number of Operations.	Recoveries.	Deaths.	Mortality per cent.
Nephrorrhaphy	9	9	0	0
Nephrotomy	10	9	1	10
Nephrolithotomy	7	6	1	14
Nephrectomy	25	18	7	28
Exploratory exposure	1	1	0	0

The table gives a total of fifty-two operations upon thirty-eight patients. In order to make the list complete, of necessity, several previously published cases have been included.

The mortality from nephrectomy, if divided according to cause, is as follows:

TABLE III.

Diseases.	Cases.	Deaths.	Mortality per cent.
Calculi	5	0	0
Abscess	6	2	33
Hydronephrosis	2	0	0
Tuberculosis	6	2	33
Cysts	3	1	33
Neoplasms	3	2	67

Most of the fatalities occurred in the earlier years of kidney surgery. During 1896–7 I performed ten nephrectomies with but one death, and the last six patients all recovered.

NEPHRALGIA—EXPLORATORY NEPHROTOMY.

The principal symptoms of kidney disease which admit of such varied interpretation as to beget obscurity in diagnosis are pain and renal enlargement. With these present, or sometimes with the association of other urinary and renal disturbances, such as hemorrhage, etc., we are compelled, in order to make a satisfactory solution of the diagnostic mystery, to resort to an exploratory incision. Of the various conditions which lead to this action none are more interesting, because none are more puzzling, than those placed under the ample cloak of nephralgia.

The benefit obtained from these indefinite and exploratory operations and in those of like nature performed elsewhere in the body, notably in the abdomen, has been attributed by some surgeons to the operation *per se;* but this explanation needs itself to be explained. Since a renal incision in certain instances relieves, as Harrison reports, the congestion due to ordinary nephritis, it is more than probable that in nephralgia a similar relief follows incision. This, however, does not explain the few cases where relief has been obtained by the simple splitting of the fat envelope and mere palpation without incision of the kidney. Some have thought that the improvement in such cases might result from the division of nerves encountered in the wound area; but in the few instances reported more light is required.[1] The mechanical handling or palpation of a kidney during its exploration may also aid in dislodging minute calculi, and thus relief be afforded. One of the following cases (Case I.) seemed to admit of this explanation.

Of course, when there is intermittence in the attacks of pain or enlargement, the influence of a loose kidney, its production of temporary hydronephrosis, which is often overlooked at the time of an operation, is to be kept in mind, particularly as this is a condition likely to be benefited by the fixation induced by an exploratory operation.

It is, however, known to all that the apparent absence of a calculus, the commonest cause of persistent pain, does not prove that it is not present. Morris has recorded a typical example of this condition, when, even after the removal of the kidney, a stone the size of a marble could not be localized by palpation. In Case III. a nephrotomy and exploration of the pelvis and ureter by a flexible metallic bougie, and also by the finger introduced into the cavity of the organ, while counter pressure and palpation were carefully made by the opposing finger (bidigital examination), failed to detect any lesion, yet a recurrence of the pain led me subsequently to extirpate the organ. Three tense hemorrhagic cysts were found which had caused the patient's trouble.

CASE I. *Renal Colic—Hysteria (?)—Exploratory Exposure—Recovery.*—Mrs. P., aged thirty-five years, was referred to me by Dr. H. C. Coe. During 1884 she had an attack diagnosed as renal colic, and in June, 1886, she suffered from occipital neuralgia and showed a marked hysteric tendency. She then continued in excellent health until January 1, 1887, when she was awakened one night with a severe darting pain in the left lumbar region. The pain radiated to the left groin and was spasmodic in character. During the intervals between the spasms, there was a steady aching pain in the loin. There was vomiting from the onset. For a few days previous to the attack the urine had contained considerable "brick-dust" sediment, but after its beginning very little urine was passed; it was of high specific gravity, contained numerous uric-acid crystals and quantities of urates, but no albumin, blood, or casts. This condition lasted a week, the spasms recurring at irregular intervals. Scarcely any liquid was retained, and sleep did not average more than two to three hours daily. From sixteen to twenty ounces

[1] Tuffier, *La Semaine Med.*, 1893, p. 481.

of urine was passed in twenty-four hours. The temperature was at no time above 100° F.

I first saw the patient on January 6th. She had not had a spasm for a couple of hours, and appeared comfortable. With the first deep pressure into the left side of the abdomen such a spasm of pain was produced that it was necessary to induce profound anesthesia before proceeding with the examination. Its results were negative, but the patient slept four hours after the ether narcosis and seemed easier. Then the vomiting recurred, and as the pulse became weaker and the condition of the patient indicated impending exhaustion, nephrotomy was decided upon and performed January 8, 1887.

The left kidney was exposed by a vertical lumbar incision and freely separated from its fatty sheath. Nothing was detected by thorough palpation of the anterior and posterior surfaces of its pelvis and of the ureter as far as it could be followed. An aspirating-needle was thrust into the kidney in several places, but nothing but blood was found. As the kidney had been so well separated from its fatty sheath, two tubes were placed, one above and one below the organ, for drainage, and the wound was elsewhere closed by deep and superficial sutures. At the close of the operation the patient was in a critical condition, having a thready pulse of 160 or more. The condition gradually improved under the administration of stimulants subcutaneously and *per rectum*. Vomiting was persistent, and nutrient enemata were continued more or less regularly during the following week. The wound healed promptly, and the condition of the urine improved. From the moment the patient recovered from the ether narcosis the attacks of pain vanished.

The hysteric element came out strongly during convalescence, and on several occasions the patient convinced herself, her family, and her attending physician that she was about to die. Sixteen days after the operation, when the wound was almost healed and the urine had been normal some days, and the patient was in good spirits and eating and sleeping well, and sitting up each day, she was suddenly seized in the middle of the night with a pain in the right side exactly like that which she had had on the left. Much to her disgust, she was immediately etherized, and the pain disappeared and did not recur. The patient died during 1890 of pneumonia, having been in good health up to the time of the last illness.

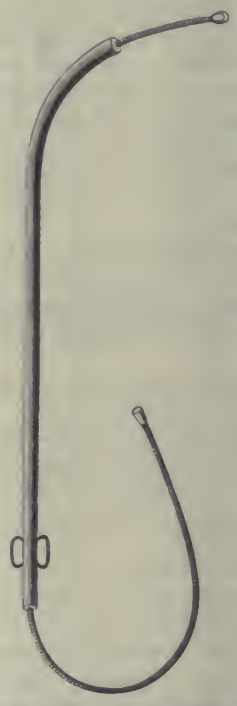
CASE II. *Nephralgia—Supposed Calculus—Movable Kidney — Nephrotomy — Nephrorrhaphy—Recovery.*— Mrs. R., aged thirty-five years, and the mother of four children, the youngest being thirteen years of age, noticed, during the spring of 1891, a soreness in the right side of the abdomen near the navel. During the summer of that year the amount of urine was unusually small. She never passed any gravel. About February, 1892, she began to have severe pain in the right lumbar region, extending into the right groin. The urine was much diminished in quantity, and contained mucus and some pus, but no blood. When I saw her, March 1, 1892, with Doctors H. C. Coe and H. F. Walker, the tenderness was exquisite and paroxysmal, any change in position or any starting of the abdominal muscles sufficing to bring it on. The greatest pain was felt over the edge of the right quadratus muscle, near the ribs, and also about the middle of the right rectus. Under ether, neither the kidney nor the ureter could be felt. The uterus and appendages were normal. The conclusion was drawn that a calculus was impacted either in the kidney or ureter.

Before examination the temperature was normal and the pulse 118; during the twenty-four hours following examination the patient was free from pain, and the urine increased to a total quantity of twenty ounces. The pain then returned, and the urine greatly decreased in quantity.

Operation being finally agreed upon, March 10th, by means of vertical lumbar incision, the kidney was exposed. It was enlarged to one and a half times the normal size. It was probed with a steel hat pin, but the presence of a stone was not detected. Traction showed it to be abnormally movable. It was slightly deeper in color than a normal kidney. An incision was, therefore, made into the kidney pelvis through the lower part of the cortex, and, by means of the finger and a sound, the pelvis and all of its calices were systematically examined.

The ureter was next investigated. After passing a large floss silk thread through the kidney for the purpose of traction, the angle between the wound into the pelvis and the uterer could be so far obliterated as to admit of the passage of a curved steel sound. [Traction by means of a thread passed through the lower portion of the kidney answers the same purpose in probing the ureter as does putting the head well back in esophageal instrumentation.] A solid instrument could in this way be passed six inches

FIG. 1.



Open-end catheter and flexible metallic ureteral probe.

down the ureter. A flexible probe thirteen inches long, made by winding a narrow, flat steel strip spirally upon itself (Fig. 1), was passed its full length without detecting a stone. A catheter in the bladder detected nothing, but drew off some blood, thus establishing the pervious condition of the ureter. There was, therefore, a perfect demonstration that the trouble was due to a movable kidney, and a kinking of the ureter, thus probably obstructing its lumen. The wound in the kidney was closed by catgut sutures, and a strip of its capsule an inch broad was removed from the whole posterior surface, and the organ stitched with silk to the muscular and fascial edges of the wound. The wound was left open, and stuffed with iodoform gauze.

The patient's condition progressed satisfactorily. Further clots and blood were drawn by catheter the evening

following the operation. The urine constantly increased in quantity, being 28 ounces in the first twenty-four hours. The paroxysms of pain were greatly lessened, and by the third day were altogether absent, while the urine had already risen to 40 ounces daily. April 27, 1897, the patient's physician, Dr. Coe, wrote that there had been no recurrence of the paroxysms of pain, but that a more or less constant pain in the lumbar region had been present, which varied in intensity at different times. The urine was occasionally reduced from 20 to 24 ounces (her normal amount) to 12 to 16 ounces. A strong current of electricity through the loin promptly relieved the pain and "ischuria." The general health continued excellent.

CASE III. *Renal Colic—Hemorrhagic Cysts—Nephrotomy—Subsequent Nephrectomy — Recovery.* — Thos. B., aged thirty-two years, suffered during six years with sharp attacks of lumbar pain, growing more frequent and more severe. Upon entrance to the hospital, February 21, 1893, nothing could be ascertained by physical examination except tenderness on pressure over the left lumbar region. The urine contained a little blood and pus.

March 1, 1893, the left kidney was exposed by the incision recommended by König, passing along the edge of the quadratus lumborum muscle to just above the ilium, and then forward along the crest of this bone nearly to the anterior superior spine. The presence of stone could not be determined by means of needle punctures or the finger. The cortex was incised, and the pelvis and eight inches of the ureter exposed without other result than a profuse renal hemorrhage, which cut short further investigation. This was so severe that it was necessary to partially fill the wound in the kidney with gauze. Seven days later, under ether narcosis, the kidney and ureter were again exposed, but nothing was found. The sinus rapidly closed, and until the patient's discharge from the hospital, five weeks after the first operation, there was no recurrence of the painful attacks.

He was again seen during December, 1896, when he reported at the Vanderbilt Clinic, complaining of a recurrence of pain, which showed itself soon after the wound had healed. March 1, 1897, acute pain like the puncture of a needle was still felt on pressure under the twelfth rib near the line of the quadratus lumborum muscle. There was no enlargement of the kidney, and the urine was clear, although at times it was said to be slightly bloody. There was a slight hernial bulging in the cicatrix on coughing and expulsive effort.

The pains increased, radiating from the loin to the breast, groin, and testes, and accompanied with chills and nausea, so that nephrectomy was performed March 25, 1897. König's curved incision was employed. The kidney was so firmly adherent that the peritoneum was twice torn through in the attempt to separate and remove the organ. These openings were at once sutured. The pedicle of the kidney was tied *en masse* with silk, the ligature including the loop of a cautery-point (Cleveland's method), so that the silk could be subsequently divided by simply passing an electric current through the cautery-point. The wound was partly closed with deep sutures of kangaroo-tendon and skin sutures of silkworm-gut and silk. The Mikulicz packing was removed on the third day. The ligature was divided and removed on the seventh day.

Examination of the extirpated kidney showed that it contained three hemorrhagic cysts, each the size of a large marble, and also that it was somewhat inflamed. There was no evidence of tuberculosis.

The patient recovered well from the operation, and resumed his work. He suddenly died, August 9, 1897, the cause of death being heart failure, according to the report of the coroner.

CASE IV. *Renal Colic—Exploratory Nephrotomy—Recovery.*—Samuel J., aged thirty-six years, entered the hospital, November 12, 1897, with the following history:

He had had three attacks of gonorrhea, occurring respectively 9 years, 2 years, and 6 months previously, and recovery always ensued without complications. One month before coming under observation there had been a sudden attack of severe pain in the right lumbar region, followed by vesical irritation, chill, fever, and sweating. Subsequently there had been two such attacks. The urine contained ten per cent. by volume of pus and albumin. Pressure over the right loin was painful.

König's curved lumbar incision was made, as in Case III., and, the kidney being exposed, an incision was made into its pelvis, but nothing abnormal was found. The ureter was also exposed for a short distance and explored by the flexible probe with a negative result. The wound was closed over gauze drains. The effect of the operation was slight. There was blood in the urine at first, and the albumin and pus were diminished for a time, but later increased again, up to eight per cent. by volume, and there was considerable purulent sediment. The wound was superficial at the time of the patient's discharge, and he has since passed from observation.

CASE V. *Renal Pain—Nephrotomy — Nephrorrhaphy—Recovery.*—Ellen W., aged twenty-two years, suffered during five years from attacks of pain and tenderness in the right lumbar and iliac regions, which were not relieved by removal of the appendix, performed at Roosevelt Hospital. The seat of tenderness and pain was along a tract running from the right kidney to the bladder. Examination, with and without an anesthetic, revealed nothing further. The urine was pale, acid, clear, with a specific gravity of 1020, and contained neither albumin nor sugar, and no pathologic sediment.

October 16, 1896, the right kidney was exposed, probed by needles, incised, and examined. A probe was passed seventeen inches into the ureter, and it was palpated as far as possible. Nothing abnormal was found. The renal wound was sutured, and the kidney itself anchored in the incision in the loin by means of catgut sutures. The lumbar wound was closed by sutures. The patient made a good recovery, and during some months was free from pain; but when seen in March, 1897, she complained of pain in the old situation and down the front of the thigh, though she was not prevented from following her occupation as a silk-weaver, standing on her feet ten hours daily. The kidney was in place.

December 10, 1897, she again returned to the hospital, still complaining of pain over the right kidney, which on examination seemed to be enlarged and tender. There was no elevation of temperature and no abnormal deposits in the urine.

MOVABLE KIDNEY—NEPHRORRHAPHY.

At a time when the kidney was still *terra incognita* to most surgeons, the attempt to relieve the pain caused by a wandering kidney by anchoring it in the loin excited a widespread interest. Like other diseases to which general attention has been directed, this condition has proved to be of frequent occurrence,[1] [2] and the operation for its relief has become almost a routine performance. During 1883 an

[1] Glénard, *La Presse Méd.*, Belge, xli, p. 65, 1889, says that sixty per cent. of 215 women had movable kidney.

[2] Mathieu, *Ann. des Malad. des Org. Gen.-Urin.*, xii, p. 70, 1894,

account[1] of one of the first successful attempts of this character was published (Case VI.). Although over fourteen years have passed since this operation was performed in the case referred to, there has been no recurrence of the difficulty, and the patient is reported to be in good health. In this, as in Case VII., the capsule of the kidney was simply stitched to the wound, while in the cases operated upon more recently a strip of the capsule has first been peeled off, in order to give a wider band of adhesion.

CASE VI. *Movable Kidney—Nephrorrhaphy—Recovery.*—Eliza I., aged thirty-three years, the mother of several children, entered New York Hospital during December, 1882, for relief from constantly recurring attacks of pain and nausea. She attributed her trouble to a concussion of the abdomen, received five years previously, when she was caught between two slowly moving cars. At that time she was confined to her bed for a brief period, and then resumed her work. Five weeks later she began to have pains in the right abdomen, running up the side and down the thigh, and soon after a tumor was observed in the right lumbar region, the manipulation of which increased the pain. Occasionally an attack of pain was followed by hematuria or uterine hemorrhage, and attacks of nausea and vomiting coincidently occurred. By crowding inward the lower ribs the kidney was easily displaced and palpated at the level of the umbilicus, with its hilum upward and its long diameter transverse. Several examinations of the urine showed it to be normal.

November 18, 1882, the patient was turned upon her face and a vertical incision made from the twelfth rib to the crest of the ilium, about three inches to the right of the spinous processes. The overlying tissues were divided and the kidney exposed, seized, and crowded into the wound. The mobility upward and downward was nearly four inches. Its capsule was stitched to the wound by means of seven carbolized catgut sutures, and the wound left open to granulate. Healing was complete within five weeks, and the patient's condition was much improved. May 12, 1897 (fourteen years later), the patient was reported to be in good health and free from her former affection.

CASE VII. *Movable Kidney—Nephrorrhaphy—Recovery.*—Augusta K., aged thirty-four years, suffered with paroxysms of pain in the right side of the abdomen during sixteen years, growing more frequent and more severe. Two years before admission to the hospital an ovariotomy was performed, but without relief. Examination showed the presence of a smooth, movable, and tender kidney. The urine was normal.

December 14, 1889, an incision extending obliquely forward and downward was made in the right loin, and the kidney exposed. After removal of part of the fat capsule, the kidney was sutured in an elevated position with strong catgut to the muscle and fascia of either edge of the wound; the incision was partly closed. After the operation the patient complained of great pain, similar to that which had characterized previous attacks. In time this somewhat subsided, but was still present at the time the patient was discharged, five weeks after operation. An abscess subsequently presented itself in the lower part of the cicatrix, and after the discharge of its contents the pain disappeared. February 27, 1897, the patient reported that she had had no further symptoms referable to the kidney.

CASE VIII. *Movable Kidney—Nephrorrhaphy—Recovery.*—Frances S., aged thirty years, referred to me by Dr. E. Cushier, entered the Woman's Infirmary with a history of general disturbance during one year, with occasional sharp attacks of epigastric pain. A movable kidney was found which was not benefited by compress and bandage, and an operation was performed May 8, 1894. An incision was made along the outer border of the quadratus muscle, and the kidney exposed. A strip of its capsule, 1.5 inches wide was removed from the posterior surface of the organ, and the kidney was sutured in the abdominal wound with chromicized catgut. The external wound was closed over gauze drains, and it promptly united. Recovery, according to a report from her physician two years afterward, was satisfactory and permanent.

CASE IX. *Movable Kidney—Nephrorrhaphy—Recovery.*—Margaret H., aged forty-two years, was troubled during two years with intermittent pain in the right hypochondriac region, disappearing on lying down. She had noticed a movable body in the right side of the abdomen. Examination showed that she had a characteristic movable kidney on the right side, which could be grasped and pulled upon, thereby causing the same pain which she described as having suffered spontaneously; the urine was normal.

January 5, 1895, the right kidney was exposed, and a strip of its capsule 4 x 1.5 inches was peeled off and six kangaroo-tendon sutures were passed through the substance of the kidney, fastening it into the wound. The end sutures were passed through the skin as well as the kidney, thus partly closing the wound, which was elsewhere filled with iodoform gauze. Recovery was uneventful. The gauze was removed on the fourth day, and the wound rapidly healed by granulation. The patient has passed from observation.

CASE X. *Movable Kidney—Nephrorrhaphy—Oophorectomy.*—Mrs. S., aged twenty-eight years, was referred to me by Drs. Roberts and Nammack, with a history of attacks of pain radiating from the right kidney all over the right side, and sufficiently severe to confine her to bed several days at a time. The assumption of the recumbent posture did not give relief. During March, 1896, she had such a severe attack, characterized by such marked symptoms referable to the right iliac fossa, that two able physicians agreed that the trouble was appendical in origin, one advising operation and the other being against interference.

When seen by me, during May of the same year, examination of the right iliac fossa was negative, but she undoubtedly had a floating kidney and also a painful ovary, prolapsed into Douglas' cul-de-sac. There was no abdominal distension characteristic of enteroptosis. In June, 1896, the kidney was replaced and stitched into position after Tuffier's method, and an enlarged and cystic right ovary removed at the same time. The patient made a prompt recovery, and when seen fifteen months later, the kidney was in good position, but the paroxysms had recurred in a somewhat abated form. In the absence of a definite lesion I was obliged to lean upon her description of the attacks. I advised an exploratory operation for the examination of the previously suspected appendix. This was recently done by another surgeon, and the appendix was removed.

CASE XI. *Movable Kidney—Nephrorrhaphy—Recovery.*—Helena L., aged thirty-six years, had complained for years of gastric indigestion and pain in the stomach and bowels, recently increasing, and especially severe after exertion, or when standing for any length of time. There was at times difficulty in micturition, and the amount of urine daily passed greatly varied. During the six months previous to examination the patient had observed a tumor

found that of 306 women, 85, or twenty-eight per cent., had movable kidney.

[1] Weir, *New York Med. Jour.*, February 17, 1883.

in the right side of the abdomen. Both kidneys could be felt as low down as the iliac fossæ.

June 9, 1896, an incision was made along the outer border of the left quadratus lumborum muscle. A rent into the peritoneal cavity exposed the spleen. This opening was closed by catgut, as was another in the pleural cavity which occurred when the incision was extended upward. The left kidney was then freed from its surroundings, dislocated into the wound, and a portion of its capsule, ¾x2 inches, was removed. The kidney was sutured to the muscles with kangaroo tendon, and the wound partially closed with silk. A similar operation was performed on the right side, and the right lobe of the liver was found to be enlarged three or four inches in a downward direction. Both wounds healed promptly, and recovery was uneventful.

March 8, 1897, the patient reported that she had no pain in the right side, but a great deal in the left, and especially a pulling sensation on stooping.

These six patients, with seven operations (*i.e.*, in one a double nephrorrhaphy), all recovered In no instance, so far as can be ascertained, did recurrence take place, and the elapsed time varies from one to fourteen years. One patient upon whom double nephrorrhaphy was performed suffered from pain in one side following the operation; in others, the pains continued though the kidney remained fixed. These results are no better than the careful surgeon should expect, but they are somewhat better than the average. Thus, according to Neumann, who published a dissertation on this subject at Berlin in 1892; out of 274 nephrorrhaphies, 5 patients or 1.8 per cent. died; while 222 patients, the histories of whom were followed for a time, 65.3 per cent. were cured, 10.3 per cent. were improved, and 22 per cent. were not improved. McCosh[1] found 3 deaths from operation in 117 reported cases of nephrorrhaphy. Of the 62 patients of whom a record was given after a lapse of three months or more, 55 per cent. were cured, 25 per cent. improved, and 20 per cent. not improved. Albarran collected 374 cases with only 4 deaths; Küster had 1 death in 50 cases, and secured 60 per cent. of cures. The latter figures are probably more reliable than those collected from many sources, since fatal cases are apt to be omitted. The mortality from this operation has usually been due to septic peritonitis, this occurring either when the transperitoneal route was selected, or when an accidental opening was made into the peritoneal or pleural cavities.

Relapses may be frequently expected, since the renal ptosis is but one symptom of the general enteroptosis so clearly described by Glénard, and of which the distended stomach or overloaded colon, are usually prime factors. It may also be stated that in none of my cases did bandages or pads give any relief; indeed, I have never observed a good result follow the application of external support.

Numerous operative procedures have been advocated for the relief of a movable kidney. Their number and slight variation, one from the other, show that something more than anchoring the kidney is often required for the relief of the dyspeptic, neurasthenic, and painful symptoms which characterize this affection. The pain may be most easily removed, but the neurasthenia is often unchanged.

[1] McCosh, *New York Med. Jour.*, 1890, vol. 51, p. 281.

As an instance of the remarkable operative feats which have been attempted in this connection, it is sufficient to mention that Riedel[1] is said to have several times stitched the kidney to the diaphragm and quadratus lumborum muscle. Others have imitated him in dislocating the kidney and suturing it to tissues, muscular and otherwise, distinct from the proper renal bed. The secret of success in operating, however, seems to lie in two points, *viz.*: careful stitching of the organ into the depths of the lumbar wound by material which will maintain its integrity a considerable length of time; and allowing a portion, if not the whole wound, to heal by granulation, in order to secure a broad cicatricial support.

In about three-fourths (78 per cent.) of the cases reported by Albarran, the kidney was sutured without the decortication suggested by Tuffier, and he protests strongly against this stripping off of the capsule, as likely to produce a considerable degree of renal sclerosis. Guyon is of the same opinion, contenting himself with the passage of the supporting sutures through the kidney substance. These sutures are usually placed, three or four in number, transversely through the organ; but lately it has been advised to make two of them longitudinal stitches, to be fastened to the muscles on either side of the incision. In my later cases I have employed the decortication already described, and have not found, in several of the patients examined at remote periods, any albumin in the urine or any other indication of renal disease. If such should occur it would as likely as not be due to the suture as to the decortication. But the latter can, in my judgment, be omitted, provided the wound be kept fairly open so that the granulations make a broad band of adhesion.

To illustrate what should not be done, however, attention is directed to the procedure of Küster who, in twelve cases, sutured the lower end of the kidney to the twelfth rib with silver wire. The result was good in ten cases, but five times he opened the pleural cavity during operation, although, thanks to his skill, no bad results followed this accident. Holl long ago called the attention of surgeons to the possibility of this mishap in work in this region, on account of the low attachments of the pleural sac. As far as possible, the fat capsule should be dissected away. A point of importance is a prolonged and, at first, quite rigid rest in the recumbent posture. This, I insist, should continue at least four weeks.

The patients upon whom I have operated have all been females. It is rare, indeed, that a man seeks relief for a wandering kidney.

If a movable kidney cannot be felt in the recumbent or lateral position, it is well to adopt a method of examination which has given me good results for many years. This consists in placing the patient in an erect position with the hips steadied against a solid table, and the head and trunk inclined forward with the hands resting on the back of a chair, or on the shoulders of the surgeon who sits or kneels in front of the person examined. This will relax the abdominal wall and allow of its free palpation, and particularly of the parts overhung by the ribs.

(To be continued.)

[1] Reineboth, "Inaug. Diss.," Jena, 1892.

MEDICAL PROGRESS.

Relation between the Testicle and Prostate.—FLODERUS (*Deut. Zeit. für Chir.*, vol. 45, p. 110, 1897) says that as extirpation of a single testicle is often followed by atrophy of the corresponding side of the prostate gland, it must be due to some nerve relation between the two rather than to any altered internal secretion. Removal of both testicles before maturity interferes with the full development of the prostate. That castration after full maturity will reduce a normal prostate is in dispute. If it does so, it reduces the volume and elasticity of the organ, and increases its consistency. The effect of complete castration in beginning, or fully developed hypertrophies, is irregular, and often not demonstrable. The reduction in volume is sometimes confined to the upper part of the prostate, and is accompanied by a loss of elasticity. while in others a shortening of the urethra is noticeable. Tuberculous processes in the gland may be brought to a standstill, or even cured, by castration.

Unilateral castration sometimes produces in the corresponding side of the normal adult prostate such changes as have been above described. It will not prevent future hypertrophy. Its effect on existing hypertrophy is slow, and consists in a shrinkage of the corresponding side, especially in the upper portion of the gland. It may cause healing of tuberculous lesions. Unilateral castration is not followed by a demonstrable reduction in size of the opposite lobe of the prostate. There usually results atrophy of the seminal vesicles, with compensatory hypertrophy of the other testicle (and prostatic lobe?). The advantages of double over unilateral castration are, therefore, plain.

Periostitis Following Muscular Exertion.—DENT (*The Practitioner*, October, 1897) calls attention to the complex of symptoms which may follow the unfair use of a single muscle, or particular group of muscles. Under such circumstances it is not the muscle itself nor its tendon which suffers, but the investing fascial plane, or the periostial attachments. The constant use of muscles attached to bones produces a vascular condition of the periosteum, and a formation of extra bone. In this manner are built up the bony prominencies which are observable in the long bones of muscular individuals. The abuse of a single muscle may cause a degree of vascularity which in time may amount to inflammation in the region of the bony attachment of the muscle or its tendon. Examples of this condition are seen in persons who make long descents from mountains, or who kick violently in football games, without being used to such exertions. Dent, in speaking of a patient presenting this affection, said that "In all probability the boy had become accustomed to a bad style of play. It is curious to note that in all athletic exercises and games the most efficient play is secured by the most scientific use of the muscles; this means the adroit combination and concerted action of many muscles rather than the undue use of one or a few. Whether using a bat, a tennis-racket, a fishing-rod, or other implement of sport, it is of profound importance to adopt what is called a good style. Teachers of games rightly, and very strongly, insist upon this point. They do so in order to get the best possible results. For example, to make a good cast with a long fishing-line, or to put on what tennis-players call a "heavy cut,' necessitates a good style. The teacher is satisfied with the result if the stroke is made effectively, or the cast is a dexterous one. He may not be aware how truly scientific his instruction is, and how, by insisting upon combined action of numerous muscles, and by using leverage in the most effective possible manner, he diminishes the strain of any one particular group of muscles, or any single muscle, and distributes it over a larger number, thus most effectively preventing such disorders as form the subject of this paper."

Other instances of the occurrence of periostitis which may be cited, are that of the housemaid, who by sweeping irritates the attachment of the pectoralis major to the humerus; that of the man who by pumping inflames the attachment of the biceps to the scapula, etc. Such continued irritation may cause an osteitis. Paget mentions a case of necrosis of the humerus, and suppuration of the elbow- and shoulder-joints, following violent exertion in a university boat-race.

Complete Inversion of the Uterus.—WOOTON (*Vir. Med. Semi-Monthly*, Nov. 26, 1897) reports a case of complete inversion of the uterus occurring in a white primipara. The placenta was adherent, and the attending midwife caused the woman to stand upon her feet while she pulled upon the cord. In this way the placenta was in great part removed. Six hours later the patient was found by the physician in a state of shock, and the uterus was inverted and entirely outside of the body. Under chloroform, and after two-hours' effort, the uterus was replaced, but the woman died the following day.

THERAPEUTIC NOTES.

Therapeutic Value of Salophen.—LEHMANN (*Ther. Wochenschr.*, September 26, 1897) finds that salophen has a most favorable influence upon psoriasis. He treated the left leg of one patient with ten per cent. chrysarobintramaticin, and the right one with ten-per-cent. salophen salve. The better result was obtained with the latter method.

BAQUE found that salophen has an indisputable action upon acute and subacute rheumatism. Although it does not have as powerful an effect as sodium salicylate, it possesses the great advantage of not producing unpleasant symptoms, such as headache, dizziness, ringing in the ears, etc. It disintegrates in the intestine, and cannot, therefore, upset the stomach. It does not seem to have any better effect in chronic rheumatism than the numerous other remedies proposed. It has a powerful analgesic action, comparable to that of antypyrin or phenacetin. It appears to be of benefit in skin affections, especially those accompanied by itching. It is without disagreeable taste or smell. A medium dose is 60 grains daily, given in divided doses.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, JANUARY 15, 1898.

TEACHING THE SIGNIFICANCE AND PROPHYLAXIS OF VENEREAL DISEASES TO NON-MEDICAL STUDENTS.

IN a recent letter our Berlin correspondent comments favorably upon the lectures on "The Significance and Prophylaxis of Venereal Diseases," which, during the past three years, have been given at the University of Berlin to non-medical students. We take pleasure in referring those who may be especially interested in the matter to the letter itself (MEDICAL NEWS, January 8, 1898), as it would be difficult to give a more able presentation of the subject, or a more entertaining description of Professor Lassar's lectures.

It has become the fashion during late years to look to Germany for much that is good, and not a little that is best, but the present innovation, from a standpoint of radicalism, is apparently more consonant with American or English institutions than with Continental. We can almost hear the caustic criticism from across the water which would in all probability have followed the announcement that an American college had been the first to add to its general curriculum a course on the prevention and significance of venereal diseases—another Yankee notion!

Individual opinions are frequently a century in advance of general practices, and the establishment of such a course, not only in the university but in all higher institutions of learning, from the high-school to the college, has not lacked advocates; but, as our correspondent aptly remarks: "The candid admission, however, of the imminence of the danger to young men is not in accord with Anglo-Saxon principles generally in such matters, and so, it may be supposed, the suggestion of such a thing to most university faculties would be met by prompt discouragement." In common with our English cousins we prefer to remain only semi-cognizant of the existance of immoral practices—a frank exposition of the question might shock some one's venerable idea of modesty.

While teaching our young men and women many useful things, we neglect, for no substantial reason, to inculcate the fearful lesson of venereal diseases—the most preventable of all; fail to teach them how to avoid paresis, tabes dorsalis, stricture, sterility, and all the fell host that surely follow indiscriminate venery; how to avoid the species of homicide, conceived in the womb of ignorance, which unwittingly sacrifices wife and children; and last, though none the less true, that the most careful therapeusis is not infrequently absolutely inefficacious in preventing the remote consequences of venereal infection.

We flee the presence of the leper, but allow the syphilitic freedom to menace us, each and every one—to drink from the same cup, eat from the same dish, occupy the same chair in the barber-shop. The physician and the health-officer are in an altercation about the disposition of a case of measles; the syphilitic slips between the legs of both.

The data of venereal diseases are so familiar to physicians that we, as a class, fail to read their real meaning—that the least we can do in order to avoid culpability in the possible wreck of a fellow being is to energetically assist in the furtherance of the teaching that every young man and woman should be sent out into the world free to choose, knowing all the facts in the case, whether or not the path will be followed that leads to suffering, invalidism, the hospital, or the insane asylum. Then, at least, we would not have to bear with equanimity the reproach: "Had I but known all." Innocence that implies ignorance of the principles of correct ethics is never

admirable, but rather always lamentable, and the peculiar attitude of the human mind that leaves one's sexual environment to be imagined had best be eradicated, and this almost herculean task no profession is better able to handle than ours.

The positive isolation of the cause of syphilis will no doubt be intensely interesting medically, but it is hardly necessary to a system of rational prophylaxis of *lues venerea*.

We forestall reference to the proverbial moral laxity of medical students, a laxity seemingly paradoxic when considered in relation to the knowledge they are supposed to possess but which, our observation justifies, grows every year less obtrusive; in fact, it may be said that progress in medical-student morality goes hand in hand with a constantly higher standard of qualification for entrance to the medical college. In this connection we may utilize the truism that constant familiarity with danger begets carelessness in its presence. This may in a measure explain the medical student's fearlessness in exposing himself to venereal infection in spite of an evident knowledge of the subject.

However, we can hardly expect to educate the "Old Adam" entirely out of existence; what we may do, and what it is our plain duty to do, is to teach the significance of venereal diseases, that it may not be said that as a profession we stand idly by and watch the mechanism of the trap in which youth is caught without once trying to injure its evil perfection; content, as it were, to sit in the curule chair without exercising the perogative—the duty of him who occupies it.

THE JUSTIFICATION OF THE PEDIATRIST'S EXISTENCE.

OUR Berlin correspondent remarked in one of his recent letters that the specialty of pediatrics has contributed nothing to the enrichment of medical science, particularly of therapeutics, during its existence now approaching a half century. This may appear on first sight to be a gross exaggeration, nearing falsehood, yet when the matter is carefully considered its truthfulness seems to be in keeping with its candor.

There are undoubtedly many physicians well versed in the ailments of childhood who do not wish to be regarded as specialists, and who maintain that pediatrics can in no wise be considered a specialty. Nevertheless, the existence of a constantly increasing number of physicians who devote their time exclusively to the treatment of diseases of children and to teaching their art to others shows that many are not adverse to the garb and cult of specialism.

Moreover, those who devote themselves enthusiastically to diseases of children are continually bewailing the fact in public that too little attention is given to their departments in the undergraduate medical schools, while they point with pride and in terms of general exaltation to the benefit which has accrued the "assumption of the dignity by pediatrics as a special department in colleges." To quote further from a recent writer in *Pediatrics*, as a result of establishing special professorships of pediatrics in medical schools, he says, "A field of inquiry has been opened by those who have given this subject earnest attention which has been fruitful in its results and which must inevitably reclaim thousands from an untimely grave." That there is a general air of conviction in such swinging statements no one can deny. But what is the justification for them, one is led to ask? Can such a writer as the one whom we have just quoted descend from generalizations and enumerate specifically some of the measures now utilized in the handling of the infant which reclaim thousands from an untimely grave and which we owe to pediatrists or their teachings? Or must they admit, with our correspondent, that their existence has been more barren of results than that of any other specialty? Have they by their own efforts altered in any way the mortality statistics of diseases peculiar to children? Have they contributed one diagnostic help in the recognition of the more obscure conditions sometimes afflicting children? Have they unraveled any of the mysteries obscuring the pathogenesis of such a common disease as Sydenham's chorea, or such an obscure condition as diabetes in children? True it is that they may point with pride to the present status of the treatment of diphtheria, but they will scarcely contend that they did more in bringing about this fortunate condition than to follow the road pointed out to them by one working in an entirely different field. They may suggest that the different forms of meningitis and other intra-

cranial and intraspinal conditions may be differentiated early, and thus the proper measures employed for their relief. With this every one must agree but Quincke, Fürbinger, Freyhan, and the others to whom we owe our knowledge of the efficaciousness of such measures and who are not particularly interested in pediatrics.

The subject of infant-feeding demands consideration. Until one examines the proceedings of pediatric societies and the files of pediatric journals he has no idea of the amount of time and energy which is consumed every year in learning and teaching how to feed babies. No one will deny that we are more adept because of this desirable possession than we were a few decades ago, yet it would be a mistake to flatter ourselves that a satisfactory stage has yet been reached. Within the memory of almost the youngest of the present generation three or four quite individualized waves have swept across the pediatric sea in reference to infant-feeding. There was a time, and that not long removed, that artificial infant-foods came in for unmerited, but considerable praise. Later, modified milk seemed to be the thing, but it was succeeded after an interval of mingled satisfaction and distrust by the cry for sterilized milk; while to-day the contest for supremacy of this form of milk and Pasteurized milk goes on apace, with the odds very decidedly in favor of the latter. It would verily seem that Pasteurization of milk is the most fitting process to which it may be subjected at the present day to make it more nearly the ideal food which we are told Nature intended it to be. But what of PASTEUR?

Taking it altogether perhaps our correspondent has given pediatrists food for reflection; they may cease drawing the long bow and concentrate their attention on centering their arrows.

ECHOES AND NEWS.

Trephining for Apoplexy Followed by Death.—The patient recently referred to editorially in the MEDICAL NEWS as having been trephined for apoplexy, is dead. The fatal issue occurred a short time after the operation, and the autopsy revealed the presence of a blood-clot in the internal capsule—a condition forever beyond the reach of the surgeon's knife.

The Brooklyn Neurological Society.—At the annual meeting of the Brooklyn Neurological Society, Dr. A. C. Brush was elected president, and Dr. W. H. Haynes, secretary, for the ensuing year.

Doctors Ill with Diphtheria.—Dr. Frank C. Bunn of East Orange, N. J., and Dr. Harriet K. Burnet of Newark, N. J., are suffering from diphtheria as a result of infection while performing tracheotomy upon a child suffering from that disease.

Death of Dr. O'Dwyer.—Dr. Joseph O'Dwyer died at his home in New York City on the 7th inst. of tuberculous meningitis. Dr. O'Dwyer was fifty-five years of age, and was graduated from the New York College of Physicians and Surgeons in 1866.

First Medical College Lectures in America.—According to Dr. Roswell Park the first lectures on anatomy given in America were those of Giles Firman, delivered some time before 1649 in Harvard College which had been established ten years previously.

A Jewish Hospital for the Borough of Brooklyn.—The Hebrew Hospital Fund Society of Brooklyn have made application to the State Board of Charities for a certificate of incorporation for their proposed new hospital and dispensary for the use of their poorer brethren.

United Hebrew Charities of New York City.—An anonymous donor has purchased the valuable property on the southeast corner of Second avenue and Twenty-first street for the purpose of erecting there a large building for the use of the "Charities" as a headquarters, for their various industrial and training-schools.

Death from Lead Poisoning.—Four deaths from lead poisoning have recently occurred in England among enamel workers in earthenware and china factories. The enamel contains from fifteen to twenty per cent. of lead. One of the deaths was that of a young girl who not long ago was fined for not wearing the respirator provided by the firm.

The Seney Hospital, Borough of Brooklyn.—A handsome bequest has been made to charity under the will of the late George Barlow. The sum of $28,000 is thus devised for the endowment of beds and for other funds of the Seney Hospital. In addition to this there are bequests to various societies, homes, and colleges amounting to nearly $100,000.

The Hoagland Laboratory, Borough of Brooklyn.—Dr. C. N. Hoagland has again made a donation to the above-named institution, by way of a New-Year's gift, by the conveyance of a security valued at $24,000. Dr. Hoagland's benefactions to the cause of scientific research are said to have reached a figure considerably in excess of a quarter of a million of dollars during the last ten years.

Importance of Haste in Dispensary Legislation.—Authoritative information has been received from Albany that the session of the Legislature this winter will be very short. An effort is being made to fix the date of adjournment at February 15th. Under these circumstances no bill introduced later than January 20th will receive any consideration. Who is responsible for the County Society Dispensary Bill? And why has it not been introduced?

Randall's Island Hospital Alumni.—A meeting will be held at the New York Academy of Medicine, at 8.30 P.M., on the 18th inst., for the purpose of forming an Association of the Alumni of Randall's Island Hospital. All who have at any time served on the staff are requested to be present. Dr. David T. Marshall, No. 205 West 106th Street, New York City, is the Secretary.

Murder of Professor Rogers.—Dr. S. A. Rogers, Professor of Anatomy at the Memphis (Tenn.) Medical College and at one time president of the Memphis Board of Health, was shot in the back by a woman on the 7th inst., and was taken in a dying condition to St. Joseph's Hospital. Immediately after shooting Dr. Rogers, the woman sent a bullet into her own heart and died instantly. There were no witnesses to the tragedy and its cause is a mystery.

Boston Medical Society.—At a meeting of this Society, held on January 1, 1898, the following officers were elected for the ensuing year: President, Dr. S. Goodman; first vice-president, Dr. R. K. Noyes; second-vice-president, Dr. F. J. Kelleker; secretary, Dr. M. Gerstein; treasurer, Dr. V. Bychower. The subject of Medical Abuse was discussed by Doctors S. Goodman, F. F. Whittier, N. M. Goodman, G. Liebman, M. Gerstein, F. J. Kelleker, and P. Losnowsky.

Colonel Bache Appointed Professor of Military Medicine.—Colonel Dallas Bache, Assistant Surgeon-General, will be relieved from duty as Chief Surgeon, Department of the Platte on January 20, 1898, and will repair to Washington, D. C., and report in person to the Surgeon-General of the Army to assume charge of the Museum and Library Division of his office, and also to enter upon duty April 10, 1898, as Professor of Military Medicine in the Army Medical School, to which he is assigned accordingly.

Medical Requirements in Tennessee.—In a recent issue of the MEDICAL NEWS we published a note in regard to the laws of the various States regarding license to practice medicine. Dr. John M. Bass of Nashville, Tenn., writes us that Tennessee is no longer among those States which accept certain diplomas in place of an examination. A new law making an examination obligatory in order to practice medicine was passed last year, and is being vigorously enforced by the State Board of Medical Examiners.

Department of Health of the Borough of Brooklyn.—This branch of the city's service has been reposed in the hands of Dr. R. A. Black, whose title is Assistant Sanitary Superintendent. Dr. Black is reported as saying that he intends to move slowly in the matter of recommending the removal of medical inspectors, it being his wish not to see the efficiency of the department impaired by hasty action. The fact that the great Borough of Brooklyn has no medical representation in the Board of Health has led to the report that legislation will be sought at Albany to the end that a medical man may become eligible to the position of president, that one of the medical commissioners will be made the successor of the Hon. Nathan Straus in that office, and that in this roundabout way the Borough of Brooklyn will come in for an adequate representation. Dr. Black was formerly connected with the Sanitary Committee of the Department of Public Instruction of Brooklyn.

Druggist Glogau Sued.—Druggist Conrad Glogau of Jersey City, N. J., is defendant in a suit brought against him by Scott and Bowne, the manufacturers of Scott's Emulsion. Some months ago *The Western Druggist*, published in Chicago, printed an article in which it was stated that the preparation put up by Scott and Bowne was found on an analysis ordered by the Food and Dairy Commissioners of the State of Ohio to contain one-tenth of a grain of morphin to every ounce. The article in question went on to say that the presence of morphin in such a quantity rendered the emulsion prejudicial to health. Mr. Glogau read the article and cutting it out exposed it in one of the show cases in his store, so that his customers could read it. It is alleged that whenever Scott's Emulsion was asked for, he would first refer the purchaser to the *Western Druggist* story. It is further alleged that Mr. Glogau explained his conduct by saying that he wished to be on the safe side in case the services of a coroner should ever be required. Scott and Bowne claim that Mr. Glogau by his action has slandered their firm and demand $25,000 damages. They deny that morphin in any dangerous quantity is present in their emulsion.—*Jersey City Evening Journal.*

Consolidation of Chicago Medical Colleges.—At its meeting of December 29th, the trustees of the University of Chicago, in response to a petition from the trustees of Rush Medical College, voted to enter into affiliation with that college. The date proposed for the consummation of the relationship is June 1, 1898, but it is specifically stipulated that the affiliation shall be dependent upon three conditions, as follows: The first is that the board of trustees of Rush Medical College shall be reorganized. At the present time a great majority of the trustees are physicians who are at the same time members of the faculty. This is acknowledged to be an unfortunate arrangement. The new trustees will be representative business men of the City of Chicago, who have no pecuniary interest in the college. The second condition provides that the requirements for admission to the college shall gradually be increased, until, in the autumn of 1902, only those who have completed the freshman and sophomore years of regular college work shall be admitted. This proposition, which had already been adopted by the present trustees of Rush Medical College, is a most significant step in the history of medical education. The third condition relates to the present debt of the college, which amounts to $71,000. It is provided that affiliation shall not take place until the debt has been paid. The trustees of the University of Chicago assume no financial responsibility in connection with Rush Medical College. Affiliation does not mean organic union. The degrees will be the degrees of Rush Medical College, not those of the University of Chicago.

A Quarantine Convention.—The recent epidemic of yellow fever in the Southern States has led to the proposition by

Dr. W. H. Sanders of the Alabama State Board of Health that a quarantine convention be held, at which the South Atlantic and Gulf States shall be represented by delegates in every business and profession, with a view to making a scientific and exhaustive study of both the theory and practice of quarantine. The following preliminary program has been submitted by Dr. Sanders: 1. Quarantine with reference to international rights and interest. 2. Federal and State powers as to quarantine. 3. State and National quarantine as affecting commerce. 4. Quarantine as it affects personal rights. 5. Sanitary inspectors of foreign ports; what is being and can be done in this direction; sanitary conditions of foreign ports which menace us most, and what can be done to improve them. 6. Policing the sea along the South Atlantic and Gulf Coast to prevent the introduction of contagious and infectious diseases; what is being and can be done. 7. National disinfecting-stations for ships; where located; how operated; under what rules; with what results, and whether others are needed. 8. State maritime disinfecting-stations; how many; where located; how operated; under what rules, and with what results. 9. Medical inspectors of South Atlantic and Gulf seaports and coast towns to discover first case or cases of infectious or contagious diseases; how best to provide for. 10. What steps should be taken in dealing with first case or cases of infectious or contagious diseases which may reach our shores? 11. State and local quarantines; how best to adjust their relations. 12. Depopulation of infected cities; how to be accomplished, and to what points may refugees go. 13. Quarantine diseases; what are they, and how should they be dealt with? 14. Infection; how conveyed, and periods of incubation of infectious diseases. Disinfection; when needed, and how applied. 15. The mails and quarantine; how to deal with them practically when proper authority has declared that they should be disinfected. 16. Management of railroad trains during an epidemic of yellow fever from a railroad standpoint. 17. Classification of freights as to their liability of conveying infection. 18. What may be done to check the spread of and to exterminate yellow fever after it has become prevalent in a city? 19. Boards of health; of whom should they be composed, and how should they be appointed? To whom should the practical administration of quarantine be committed? 20. Practical difficulties in diagnosing yellow fever. 21. Interstate quarantine from a constitutional, commercial, and sanitary point of view. 22. Experiences of a quarantine officer in the recent epidemic. 23. National quarantine. 24. A National Bureau of Public Health. 25. The relation of the press to epidemics and quarantine. 26. Quarantine from a moral standpoint. 27. Sins and absurdities committed in the name of quarantine during the recent epidemic. 28. Introduction of yellow fever into the country in the past; from what places introduced and how.

A-Naphthol as an Intestinal Antiseptic. — For this purpose Maximowitsch considers α naphthol superior to β naphthol. It has three times the antiseptic power of the latter, and exhibits only one-third its toxic properties.

OBITUARY.

MR. ERNEST HART OF LONDON, ENGLAND.

MR. ERNEST HART, late Editor of the *British Medical Journal*, died at London, England, January 7th. Mr. Hart was born in the year 1836. He was educated at the City of London School and the School of Medicine attached to St. George's Hospital. In addition to his editorial connection with the *British Medical Journal* he was during some years co-editor of the *Lancet*. At one time he was ophthalmic surgeon and lecturer on ophthalmology at St. Mary's Hospital. Mr. Hart's great reputation however, does not depend so much upon his work along strictly professional lines as in the departments of hygiene and sanitation. Indeed, he might be called the great high-priest and indefatigable preacher of hygienic morality. He interested himself early in this work, and rendered great service in exposing defective arrangements for the sick poor in the workhouses of England, his efforts leading to the passage of an act of Parliament creating the Metropolitan Asylums Board. He carefully investigated during 1868 the practice of criminal baby-farming in London, and his report on the subject was the most effective argument in securing the passage of the Infant Life Protection Act. He also gave his powerful aid to the movement which resulted in the establishment some twenty years ago of the so-called "coffee-taverns" in London.

Not content with introducing these improved sanitary and economic measures at home, he carried the war into India and, as was said in these columns at the time, endeavored to hammer into the Mohammedan ears and understanding the great lesson of sanitation and preventive medicine upon which not only the health of the Orient but that of the Occident depends. His work in India was directed more especially against the spread of cholera through Mecca pilgrimages. His persistent advocacy of disinfection and quarantine was the most potent factor in the establishment of the international system of quarantine applied to these pilgrims. For his tireless efforts in such noble work Mr. Hart has placed the whole world under a deep debt of gratitude. Mr. Hart's more recent work is the report of the Parliamentary Bills Committee of the British Medical Association upon waterborne typhoid. In this report was presented a summary of the various outbreaks of typhoid fever in Great Britain and Ireland from 1858 to 1893. Upon this the MEDICAL NEWS commented editorially in the issue of November 27, 1897.

Mr. Hart was Honorary Chairman of the National Health Society of England and President of the Medical Sickness, Annuity, and Life Assurance Society. He was appointed editor of the *British Medical Journal* in 1866, which position he filled up to the time of his death. For several years he was also responsible for the editorial management of the *Sanitary Record* and the *London Medical Record*. To record the death of one whose contributions to the cause of advancing civilization have been as great as those of the subject of this obituary is indeed a lamentable necessity, and in closing it may be said that to this man is largely due the preeminence of England in matters of public sanitation.

CORRESPONDENCE.

TREPHINING FOR HEMIPLEGIA AND NEWSPAPER NOTORIETY.

To the Editor of the MEDICAL NEWS.

DEAR SIR: The editorial comments upon the subject of "Trephining for Newspaper Notoriety," which appear in the MEDICAL NEWS for January 1, 1898, are quite in accord with my own views on such matters—in cases to which such strictures are applicable.

Here is my brief rejoinder: It is a difficult matter to operate constantly in the presence of fifty or one hundred men without occasionally presenting something which interests them and which causes discussion outside of the class-room. I depend entirely upon the members of the medical profession for my livelihood, and whenever any of my cases are reported in the lay press it costs me hundreds or thousands of dollars. It does not disturb any of the physicians who know me personally, but it irritates physicians who do not know me, and who delight in reading such brightly caustic diction as that which appeared in your editorial.

I have several times received attention by the lay press, as has nearly every surgeon in New York City. The only case that ever came to me directly or indirectly, as far as I know, as a result of such "advertising" was a case in which I did not receive any fee for my work, but was threatened with a suit for malpractice. Other surgeons who have been placed in my position must be amused indeed at the idea of lay-press notices being classified under the head of "advertising."

The apoplexy case has not been correctly reported in the lay press or in the MEDICAL NEWS. A proper report upon the case will be forthcoming at the proper time. Meanwhile it may be well if speculation upon its character be allowed to rest. The editorial in the MEDICAL NEWS on the subject of "Trephining for Newspaper Notoriety" would do me great injury if it were not for the fact that I have so many good friends among the medical editors of the country. Although the editor of the MEDICAL NEWS does not know about me, or about my work, I assume that he would not intentionally do harm to any one, and I will be quite satisfied if he will take the trouble to address letters to the editors of the various newspapers of this city asking if their reporters obtained their information about the apoplexy case from me or from any of my assistants, or if it came from outside parties, and if he will publish the answers received.

All of the newspapers in New York City made news out of the case in question. A great many reporters came to ask about it. Out of the number I had to say something to three only. The reporter for the *World* kindly published the reasons which I gave him for physicians not being allowed to talk about their cases. The reporters for the *Times* and for the *Herald* did not mention my name, but they did publish the questions which they had put to me, and in such a way as to make it appear that I had volunteered the information. This was unintentional on their part as they were evidently gentlemen, and appreciated the reasons why I could not give them information. The "news" about the case did not come from me or from any of my assistants, as all of my friends know very well.

ROBERT T. MORRIS.

NEW YORK, January 8, 1898.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

HYGIENE OF THE SCHOOLROOM—FIRE AT THE UNIVERSITY HOSPITAL—ANNUAL ELECTION OF OFFICERS BY THE COLLEGE OF PHYSICIANS OF PHILADELPHIA, OBSTETRICAL SOCIETY OF PHILADELPHIA, AND PHILADELPHIA ACADEMY OF SURGERY—PRESENTATION OF A PORTRAIT OF THE LATE DR. KIRKBRIDE TO THE COLLEGE OF PHYSICIANS—DR. CHAS. E. SAJOUS—DR. TYSON'S RECEPTION TO THE PHILADELPHIA COUNTY MEDICAL SOCIETY—THE LATEST VERSION OF DR. EVANS' WILL—BACTERIOLOGIC INVESTIGATION OF THE WATER-SUPPLY.

JANUARY 8, 1898.

THE wave of reform which has of late swept over the health authorities of this city has extended to those having school matters in charge. Prodded on by the official hints from the former as to the need of radical improvements in the hygiene of the schoolroom, the latter officials having decided to further school sanitation by furnishing each pupil with an individual drinking-cup, by providing separate receptacles, which may be antisepticized, for each student's pencils and other paraphernalia, by prohibiting the decoration of rooms occupied by classes with potted plants and vines, and by directing that the schools in infected districts be scrubbed out weekly with carbolic-acid solutions. These details, while essential and valuable prophylactic measures, to be really effective must be supplemented by a thorough attention to school lavatories and drains, and to energetic instruction tending to impress upon the pupils (and their parents) the value of personal cleanliness and hygiene. Until the latter is done, no amount of antisepticizing and inspecting will prevent contagious diseases spreading from pupil to pupil.

A fire which for a time threatened the destruction of the hospital of the University of Pennsylvania originated in the dispensary of the hospital on January 4th, but owing to the prompt action of the hospital employees the flames were prevented from communicating to the wards. The fire originated in the basement, immediately under the men's surgical ward, and was due to the explosion of a gas-stove. Dr. Schaeffer, the pharmacist, was severely burned in attempting to keep the flames from reaching the adjoining room, where a large quantity of alcohol and benzine was stored. No unusual excitement among the patients occurred, all of whom, it is said, were ignorant of the danger. The loss is estimated at over $2000.

At the last stated meeting of the College of Physicians of Philadelphia, held on January 5th, Dr. John B. Deaver read a paper on "The Necessity for Prompt Surgical Interference in Typhoid Perforation and Appendicitis Complicating Typhoid Fever." The speaker urgently recommended immediate operation in these complications of

enteric fever, citing a number of instances from his service at the German Hospital which illustrated the advisability of this plan of treatment; many of the cases quoted were transferred to him from the medical ward of the hospital, operated upon, and then transferred back again to the medical ward, where the bath treatment was resumed, with a gratifyingly low mortality, considering the desperate character of the cases. Dr. James C. Wilson, who opened the discussion of Dr. Deaver's paper, approved in decided terms of surgical intervention in such cases, and held that a moribund condition of the patient was the only contraindication to its employment. Dr. M. B. Hartzell read a paper, entitled "Infectious Multiple Gangrene of the Skin; Report of a Case, with Illustrations." At the close of the scientific business of the evening, a portrait of the late Dr. Thomas Story Kirkbride was presented to the College by members of his family. Dr. John B. Chapin, the successor to Dr. Kirkbride as Superintendent of the Insane Department of the Pennsylvania Hospital, made the presentation address, paying the highest tribute to his predecessor's high attainments and to the advances in the treatment of the insane which he had inaugurated at the Pennsylvania Hospital. The President, Dr. J. M. DaCosta, made a speech of acceptance of the portrait on behalf of the College. At the annual election of officers which then took place, Dr. John Ashhurst, Jr., was elected president, and Dr. W. W. Keen, vice-president. On the recommendation of the Council the following were elected to Fellowship: Drs. George M. Stiles, Stricker Coles, Russell H. Johnson, and George G. Ross.

At the last meeting of the Obstetrical Society of Philadelphia, held on January 6th, Dr. Charles P. Noble read a paper on "Some of the Disadvantages of Vaginal Drainage." He quoted a group of six cases of pelvic cellulitis and abscess, in none of which had the vaginal route secured proper drainage; in two of these cases, moreover, a secondary abdominal section was necessitated in order to evacuate the purulent collections. At the annual election of officers, which followed the speaker's paper, the following were elected officers of the Society for the ensuing year: President, Dr. Charles P. Noble; vice-presidents, Drs. J. M. Fisher and George M. Boyd; secretary, Dr. Frank W. Talley; treasurer, Dr. George I. McKelway.

At the annual business meeting of the Philadelphia Academy of Surgery, held on January 3d., the following officers were elected for the ensuing year: President, Dr. J. Ewing Mears; vice-presidents, Drs. W. W. Keen and John Ashhurst, Jr.; secretary, Dr. William J. Taylor; treasurer, Dr. William G. Porter; recorder, Dr. L. W. Steinbach; council, Drs. Henry R. Wharton and Thomson R. Neilson; business committee, Drs. Richard H. Harte and DeForrest Willard.

Dr. Charles E. Sojous has resigned the deanship of the Medico-Chirurgical College, to take effect immediately. The resignation has been accepted by the trustees of the college, who elected Dr. Seneca Egbert, formerly vice-dean, his successor. Dr. Sajous' resignation was prompted by his desire to devote more time to scientific work and private practice than such an onerous position allowed him.

Dr. James Tyson, the President of the Philadelphia County Medical Society, gave a large reception on the evening of January 8th to the members of the Society. The reception was held in the banquet-room of the Hotel Bellevue, and was attended by over 500 guests.

The latest version of the will of the late Dr. Thomas W. Evans, leaves the sum of 20,000,000 francs to found and maintain a museum in this city, and to erect to the donor a statue (in one of the public squares to cost between 1,000,000 and 2,000,000 francs). The news comes from the Paris *Figaro*, and is not disbelieved by the late doctor's relatives in this city.

The Board of Health has instructed the Bacteriological Department of the Health Bureau to undertake on a large scale bacteriological examinations of water from hydrants of all houses in which there are at present cases of enteric fever. The continued large number of typhoid cases is very generally thought to be due to the polluted water-supply, and these instructions were ordered to determine, if possible, the cause of the epidemic. Diphtheria is still active, and scarlet fever and typhoid are on the increase again, as shown by the following statement of returns of contagious diseases for the week ending January 8th: New cases of diphtheria, 119, or 2 more than last week, with 25 deaths; new cases of scarlet fever, 62, or 16 more than last week, with 6 deaths; new cases of enteric fever, 165, or 68 more than last week, with 15 deaths—a total increase in contagious diseases of 86 cases over the preceding week. The whole number of deaths from all causes for the week was 475, an increase of 14 over the week before, and a decrease of 38 from the corresponding week of last year. Of the total number, 161 occurred in children under 5 years of age.

OUR BERLIN LETTER.

[From our Special Correspondent.]

THE PROPOSED LAW TO PREVENT THE EMPLOYMENT OF MARRIED WOMEN IN FACTORIES—ITS PROBABLE EFFECTS UPON INCREASE OF THE POPULATION—THORACIC ANEURISM AND PULMONARY TUBERCULOSIS—AN UNUSUAL CASE OF MECHANICAL OBSTRUCTION OF THE PYLORUS—DETECTION OF SEMINAL STAINS AFTER A LONG LAPSE OF TIME.

BERLIN, January 7, 1898.

THE German Government is nothing if not paternal, and scarcely a session of the Reichstag passes without the enactment of laws which are expressive of this tender sentiment. All interest in the Reichstag proceedings just now centers around the appropriations for the navy, but still there is occasional attention given to some of the ethical measures which it is proposed to make laws. One of these, involving the question of forbidding married women to work in factories, has attracted a good deal of attention from medical men.

The discussion has taken on a rather typically German aspect, but still presents features which seem of universal interest. It is urged that the absence of mothers from home necessitated by factory work frequently involves

the early artificial feeding of children, careless bringing up, and neglected training. From the first comes the high infant mortality which it is the effort of sanitarians the world over to lessen; from the second and third result defective physical and moral training. Deformities are acquired from accident and from increased morbidity, and constitutions congenitally healthy are undermined. The lack of the mother's constant influence is the root of much more of the weaknesses of character, of acquired bad habits, of tendencies to evil, kleptomania, dipsomania, and the like, than all the innate hereditary moral defects which have of late occupied so much attention. Besides, it is urged, excessive competition has already ruined wages. The number of those seeking employment is so great that employers can obtain ordinary hands for what are really not living wages. The gradual entrance of woman into the labor circle has only resulted in obtaining for husband and wife together what the husband alone formerly received, and the family is, of course, no better off. The exclusion of married women from factory work would lesson some of the ruinous labor competition which now exists, and lead in course of time to a better state of affairs.

The German law for the absolute exclusion of children from factories enacted in 1893 has produced excellent results, and those in favor of the new law look with confidence for corresponding results from its enactment. Germans, anyhow, have much more confidence in the reform of social conditions by lawmaking than have most other peoples, and the paternal features of their government are by no means the most unpopular ones. The proposal will, however, meet with considerable opposition, and from points of view which would be utterly unlooked for with us, but which, owing to the national circumstances over here, will throw sidelights upon the question which will probably prevent action at present.

It is argued that the modern woman's duties in the household are much overestimated. She still has the housework to do it is true, but she no longer has the spinning and making of the wearing-apparel for all the various members of the family, which once constituted the principal part of her occupation. Her duties in the care and education of her children are now transferred to schools, which, in the form of kindergartens, are begun while the child is still very young.

All this is supposed to plead for the privilege of the woman working for hire outside of her house, but the real argument of the question, the one which carries weight with the Germans, comes last. If the wife is not allowed to work then the prospective husband will be brought face to face with the fact that he must support the family alone, and with wages as they are, most workmen can scarcely afford to do this. Then he will follow the example of so many of his betters and be content to remain single, in which case Germany's at present rapidly increasing population, as has happened in France, though for other reasons, will come to a standstill. This would mean the lessening within twenty years of the available military force, and that must not happen at any cost. Everything here is arranged with a single eye to the prevention of any such catastrophe as that. So, while those interested in the health of the nation have discovered a source of danger and suggested the remedy, the projected reform is apt to fail of accomplishment.

Professor Fränkel, of the throat and nose clinic at the Charité, called attention some time ago to the frequency with which pulmonary tuberculosis develops in cases of aneurism of the aorta. He attributed this to the fact that a bronchus is probably pressed upon, air circulation and the proper aeration of blood interfered with, and the resistant vitality of the lungs thus lowered. His explanation was not accepted as readily as the facts he reported. Further observation showed the truth of his statement as to the liability to tuberculosis in aneurism, but two other explanations of the fact were presented. One was that the pulmonary artery is pressed upon, and the blood-supply to the lung being thus interfered with its tissues are predisposed to infection. Traube's observation as to the frequency of tuberculosis in cases of pulmonary stenosis, for similar reasons, has been very generally accepted. Still another explanation is that pressure on the vagus causes trophic changes in the lungs, and thus vitality is lowered. This last theory has been confirmed so often in experiments upon animals, when interference with the vagus is almost invariably followed by pulmonary disease, that it was considered very plausible.

At the last meeting of the Society for Internal Medicine, however, Professor Fränkel showed the specimens from a case which would seem to prove his theory. The aneurism was of one of the pulmonary arteries, and by pressure it had narrowed the corresponding bronchus to a considerable extent. Primary tuberculosis of the lungs existed only in the lobe to which this bronchus was distributed, while whatever disturbance of the circulation there was from the aneurism *per se* should have affected much more of the lung parenchyma.

A favorite object of curiosity and of general interest here used to be an elderly hippopotamus in the Zoological Garden. His favorite occupation, when conscious of the presence of an interested audience, used to be a series of playful antics with a rubber ball, his ungainliness making up for his lack of agility—to the amusement of the crowd. One day the ball disappeared, and shortly after the animal showed signs of not being himself. He had evidently something on his heart or his stomach. It was thought that either his failure to attract the admiration of the crowd by his playful antics weighed upon his sensitive spirit, or that the lack of exercise consequent upon the absence of incentive to effort disturbed his metabolic equilibrium and reacted upon his digestion.

Like other elaborate diagnostic theories when patients higher in the scale of evolution have been concerned, these opinions did not lead to any therapeutic result. Another ball was supplied, and every encouragement and opportunity for the resumption of his old-time activity and playfulness were furnished him, but all was of no avail. After a while he absolutely refused all food, and death from inanition closed the scene. The *post-mortem* revealed that he had swallowed the rubber ball, and that

this, by peristaltic action of the stomach, had become firmly wedged at the pylorus, absolutely preventing the passage of all food from the stomach to the intestines. The stuffed hide with the story of his tragic fate adorns a pedestal in the Zoological Museum. The accident is an extremely unusual one, but the possibility of such a thing happening in children is not entirely out of the question, so that the story seems not without interest for the medical man.

Of late a good deal of attention has been paid in Germany and Austria to the claim of a new method of detecting spermatic stains, if necessary, years after their original occurrence. Further investigation seems to show that while it is not the ready infallible method that was at first claimed it will prove of great help in such examinations. To a small amount of material scraped from the surface of the supposed seminal stain is added a little saturated Lugol's solution. If spermatic particles are present rather large, brown rhomboid crystals may be discovered with ordinary microscopic magnification. These crystals, while not absolutely characteristic of spermatic substance, as has been shown at the morgue here and elsewhere, always occur if spermatic fluid has been present. If they cannot be demonstrated after careful trials, then it is useless to go on with the often long and patient microscopic search for spermatozoids which used to be necessary. The crystals described are not a chemic combination of spermin, as at first thought, for they have been demonstrated by adding Lugol's solution to mucus from an infantile vagina, but represent a degenerate stage of certain albuminous products. Where a seminal stain exists, however, there they will always be found.

Paris.

SYPHILITIC CHANCRES OF THE FOREARM DUE TO TATTOOING—CHOLEDOCHOTOMY—A CASE OF SUBPHRENIC ABSCESS ASSOCIATED WITH THE PRESENCE OF GAS—REMOVAL OF TUMOR OF THE LIVER—ANTAGONISM BETWEEN THE POISONS OF HORNETS AND VIPERS.

AT the meeting of the Society for Dermatology and Syphilography of November 11th, FOURNIER presented a patient who had two typical *syphilitic chancres on the middle region of the forearm due to tattooing*. BESNIER referred to a question to which as yet no satisfactory answer has been given, *viz.*, how long does an instrument infected by the syphilitic contagium retain its virulent properties? It is probably only for a short time, as the instances of its transmission upon surgical instruments, caustics, etc., are comparatively rare, and in almost all of the reported cases the transfer of the virus from one patient to another has been an immediate one. It appears, therefore, that the syphilitic virus loses its power within a short time outside the human organism, and that it requires frequent transmission from person to person in order to remain active.

At a meeting of the Surgical Society, December 1st, QUENU spoke of *choledochotomy*, basing his conclusions upon six cases of his own and ninety-five others which he has been able to collect from medical literature. In four of his personal cases, the common duct was sutured. One of these patients died, and in the other three it was necessary to remove the sutures on account of biliary intoxication. Two of these patients recovered without permanent fistulæ. Two patients, in whom no suture was attempted, also recovered without fistulæ. From his experience in these six cases Quenu is convinced that the ductus choledochus should not be sutured after choledochotomy.

At the session of December 8th, LEJARS described a *case of subphrenic abscess associated with gas* and originating in a perforation of the anterior wall of the stomach. The patient, a woman aged thirty-two years, had suffered a long time from gastric troubles with symptoms simulating intestinal obstruction. Medium laparotomy was performed, allowing a great quantity of pus and considerable gas to escape from a huge pocket in the right hyperchondrium. The patient died on the fourth day, and at autopsy it was discovered that there was a second smaller abscess also containing gas and pus, situated between the stomach and spleen, and resulting from a second perforation, this one being in the posterior gastric wall. This abscess was overlooked at the operation, and from its situation it seemed doubtful whether it could have been relieved had it been discovered.

TERRIER reported the *successful removal of an epithelial tumor from the middle of the anterior border of the liver*. He made use of the method advocated by Kousnetzoff and Pensky, consisting of a system of chain ligatures, and divided the tissue of the liver with a thermocautery. Hemorrhage was in this way almost entirely avoided. The abdominal wound was left open and it rapidly granulated. POIRIER, in a similar manner, removed a nodule of cancer the size of a large nut from the surface of the liver. Hemorrhage was controlled by cross sutures, and the patient recovered readily from the operation, but died of cancer six months later.

PHISALIX, at a session of the Biological Society, December 4th, stated that the venom of wasps and that of the common honey bee produce symptoms very similar to those seen in viper poisoning. He has examined the *relationship existing between the venom of a hornet and that of a viper*, with the purpose of ascertaining whether the former does not possess immunizing properties in respect to the latter. This appears indeed to be the case, as hornet poison introduced in small doses into guinea-pigs, confers on them marked immunity to viper poison. The true nature of the virus is still to be determined.

HALLION stated that *sea-water may be employed with advantage for hypodermoclysis*, instead of a 0.7 per cent. saline solution, as has already been shown by Quinton. Diluted sea-water is better borne than salt water, for it may be administered in larger doses and injected much more rapidly. It is consequently less toxic than the solutions of salt water usually employed. It is to be noted, moreover, that sea-water reduces the temperature, where ordinary salt water raises it. QUINTON and JULIA have experimented upon dogs of all ages and under varying conditions to determinine the relative value of sea-water

and artificial serum, and in every case the results have shown the superiority of the former for subcutaneous injections. Under the influence of the injections of sea-water the renal action is better, both quantitatively and qualitatively.

MERCIER found in the urine of women in a state of eclampsia, a large quantity of albumin, which was soluble, entirely or in part, in the presence of a very small amount of acetic acid. This albumin, therefore, differs from that usually found in albuminuric subjects, more particularly from the presence of serin.

WIDAL reported to the Medical Society of the Hospitals, December 3d, a case of *idiopathic pyopneumothorax which terminated fatally*. The symptoms had existed ten days. The pleura was distended with an extremely fetid fluid, containing a great variety of micrococci and bacilli, both aerobic and anaerobic. No focus of gangrene, pneumonia, bronchopneumonia, or tuberculosis could be detected in the lung. Nor was there any trace of gangrene or perforation in the pleura. Examination of these organs, therefore, gave no clue to the origin of the infection.

GUINON, at the session of December 10th, reported that *three cases of typhoid fever had developed almost simultaneously in a certain hospital ward*. The patients were boys, aged five, six, and twelve years, who were under treatment, respectively, for acute poliomyelitis, purpura, and bronchitis. There were at the time in this ward several cases of typhoid fever. The mode of infection was not evident.

Vienna.

RESULTS OF SUBCUTANEOUS FRACTURE OF THE SKULL IN THE FIRST YEAR OF LIFE—TAMPONS INCLOSED IN GELATIN FOR USE IN THE VAGINA—HEADACHE AND ITS TREATMENT.

At the session of the Imperial Royal Society of Physicians, December 3d, WEINLECHNER spoke of the *results of subcutaneous fracture of the skull in the first year of life*. These results may be twofold in character. Either there may be a defect in the skull with attachment of the brain, or defects of the skull with false meningocele. Both forms develop from fissures. In the first form the edges of the bones are raised and thickened, and pulsation of the brain is easily detected, although with the most powerful expiratory effort there is no protrusion of the brain itself. Such defects in the skull of themselves do not produce symptoms, but they are of importance because they leave the brain exposed to all sorts of injuries. False meningocele may be emptied by pressure, which sometimes does not produce symptoms of pressure upon the brain. When so emptied, it is possible to feel a distinct wall of the cavity, as in case of a hematoma. The contents are connected with either the subdural or subarachnoid space. Both forms may be combined.

With reference to treatment, it was formerly the custom to apply pressure to such false meningoceles. This was without lasting benefit. The effects of puncture are usually transitory unless the meningocele is of very recent origin. Injections of tincture of iodin are too dangerous. The best treatment consists in splitting up the cyst and allowing it to heal by granulation. Later the defect in the bone may be remedied by an osteoplastic operation. In some cases Weinlechner said that he had used plates of celluloid with good result. One of the most interesting of these cases was one of neuralgia of the third branch of the the trigeminal nerve, in which resection was performed and a celluloid plate introduced to prevent union of the divided ends of the nerve.

At the session of the Medical Club, of December 1st, FISCHER showed *tampons inclosed in gelatin for use in the vagina*. The tampons may be saturated with any desired drug, and after their introduction the gelatin melts and the tampon comes into contact with the mucous membrane.

At the session of the College of Doctors of Medicine, November 29th, BENEDIKT spoke at length upon *headache and its treatment*. He recommended for essential headache, the iodids, electricity, and the actual cautery, the wounds made by the latter being kept open by an irritating ointment. In symptomatic headache (occurring in connection with constitutional maladies such as enemia, congestion, nephritis, etc.) treatment should be directed toward the disease itself. In hemicrania, Benedikt also recommended the iodids and faradization. Naturally, these measures will relieve, and not cure, the trouble, as migrain is a congenital constitutional affection. He employs iodids and mercurials for headache produced by tumors of the brain, as he finds these remedies have a favorable influence upon the symptoms, even when the tumor is not syphilitic. Before applying the cautery the head must be shaved. According to his view the head is too frequently trephined for pain in connection with cerebral tumors. Such treatment rests upon a misconceived idea that pressure in such cases is the cause of the headache.

SOCIETY PROCEEDINGS.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting, Held November 17, 1897.

THE President, DR. CHARLES L. DANA, in the Chair.

DR. ROBERT MILBANK presented a case of cycloplegia. The patient was a man, thirty-five years of age, who contracted syphilis eight years ago. He was put upon antisyphilitic treatment, which was continued three years without bad effect, and during this period he faithfully carried out all directions. While under treatment he had an attack of syphilitic iritis in the *right* eye, from which he finally recovered. When the treatment was discontinued he was in perfect health. In 1894, four years after the appearance of the primary lesion, he suddenly discovered that there was slight interference with the vision of the left eye. An ophthalmologic examination revealed dilatation of the left pupil, with no change in the retina or optic nerve. The pupil reacts under eserin and pilocarpin, and at such times vision is perfect. The eye trouble has not increased since its sudden onset. The man has no disorder of speech. He is strong and muscular and oth-

erwise in perfect health. The case is reported because of the sudden appearance of the eye symptom after two years of good health preceded by three years of careful anti-syphilitic treatment.

DISCUSSION.

DR. FREDERICK PETERSON: I understand that this patient has been examined only by an ophthalmologist, whereas, to my mind, the case of this man is one for the neurologist. Such a condition is often preliminary to neuritis and locomotor ataxia, and is also a manifestation of cerebral syphilis. It is frequently observed during the course of syphilis, and may come on five, ten, fifteen, or even twenty years after the other lesions. I consider it an indication for specific treatment.

DR. JOSEPH COLLINS: This condition of the pupil is so suggestive of locomotor ataxia that it is impossible to think of anything else. There is nothing remarkable in the fact that it appeared several years after other manifestations of syphilis, nor that it has neither progressed nor retrogressed since its occurrence. These symptoms often develop late and in spite even of heroic treatment. Some years ago I analyzed a hundred cases in which syphilis was a prominent element. Those patients who were treated in the most approved manner developed nervous lesions a little sooner and with more severity than those who had not been so well treated, so one cannot place much dependence upon the treatment of syphilis to cause delay in the appearance of nervous symptoms. The case in question should be carefully watched, thus anticipating the occurrence of serious brain lesions. The eye symptoms are certainly an indication for treatment by means of mercury and hydrotherapy.

DR. PETERSON: The patient is still young—only thirty-five—and the manifestations of locomotor ataxia usually come on later than this. Perhaps within three or four years from now they will develop, or he may have general paresis. I agree with Dr. Collins as to the necessity for specific treatment, especially if the eye symptoms are an indication of cerebral syphilis.

DR. MILBANK: Can it be possible that a capillary hemorrhage has occurred along the optic nerve and produced this condition? It came on so suddenly, and he tells me that his father died of cerebral hemorrhage, and had several attacks previous to the one which proved fatal.

DR. COLLINS: The visual disturbance may have gradually come on, although the patient may have suddenly discovered it. Patients often think these eye symptoms come on all at once, when in reality they have continued some time before being noticed. This is explained by the fact that they have unconsciously become accustomed to monocular vision. The condition under discussion is not an uncommon pretabitic symptom. I have had patients who complained of it during as long a period as eight years before other symptoms developed,

DR. A. M. JACOBUS presented a child, nine months old, with an extensive subdermal growth or induration of of the vulvoperineal region. The child was apparently healthy at birth, was delivered by the speaker with forceps after a somewhat tedious labor, and without injury. The growth was first noticed by the mother when the baby was two and a quarter months old, but it was not until nearly seven months later that she consulted him about the disease. According to the mother, it first made its appearance between the right labia majora and the anus, and gradually extended upward to the anterior superior spine of the ilium and backward to the coccyx. The glands of both inguinal regions were very much indurated and enlarged. A few small glands could be detected in the right cervical and axillary regions. The child seemed to be in good health otherwise, Since first seen, about three weeks ago, the disease has steadily extended. Drs. Adami, Piffard, Vissman, LeFevre, and others, had very kindly examined the case at the speaker's invitation. Various diagnoses have been made, such as granuloma (originally, perhaps), scrofulosis, epithelioma, sarcoma, and tuberculous infection of the glands. A very doubtful specific history was elicited from the father, who confessed to having had a venereal lesion, probably a chancroid, some four or five years before marriage. At that time he was seen by several physicians in a large dispensary, who said the trouble was a chancroid; while a physician in private practice had declared it to be a chancre, and had given him suitable internal treatment. So far as the father knew there had been no subsequent symptoms or trouble. The disease in the child is increasing rapidly, but, except to interfere with natural defecation, does not appear to affect it. It appears to have commenced in the vulvar glands and not in the skin. There has never been any tendency toward suppuration or ulceration. I am of the opinion that the growth is malignant, either adenoma or sarcoma, No tissue has as yet been removed for a microscopic examination. In the way of treatment the baby has been given arsenious acid, $\frac{1}{100}$-grain, three times daily, and chlorid of gold, $\frac{1}{60}$-grain, once a day.

DISCUSSION.

DR. S. H. DESSAU: If this child presents a malignant disease which has been developing ever since the child was a little over two months old, it seems to me that the baby would not be in such apparent good health. I cannot pretend to say what it is. It may be specific, although the history does not point especially to that, nor does the appearance of the lesion, for in a child of this age there would be some ulceration of the skin. I am inclined to believe, however, that it is tuberculous.

DR. J. H. FRUITNIGHT: It seems to me that an accurate diagnosis is impossible without a microscopic examination of the growth. I am inclined to think that it is an epithelioma; it certainly has the appearance of malignancy.

DR. R. C. M. PAGE: I would like to suggest the possibility of it being Hodgkin's disease, which is characterized by a widespread involvement of the glands. I once saw a case occurring in a boy nine years of age. He was also seen by the late Dr. Henry B. Sands, who refused to operate because the glandular involvement was so extensive and because of the proximity of so many important blood-vessels. I would suggest that the child's spleen be examined, for in Hodgkin's disease there is usually enlargement of this organ; there is also not only a deficiency in the number of red blood-corpuscles, but,

in time, an increase in the white. The disease remains stationary during a long period, and will all at once be characterized by rapid changes.

DR. BULKLEY: I have never seen malignant disease in a child so young, and I do not think it is epithelioma or carcinoma. It strikes me as a local infective process. There are present many of the features we observe in sluggish conditions, which we now recognize as tuberculous.

DR. A. M. JACOBUS then read the paper of the evening, entitled

A CASE OF INFANTILE SCURVY, WITH COMMENTS ON INFANT FOODS AND INFANT-FEEDING.

(See page 68.)

DISCUSSION.

DR. S. BARUCH: I have seldom heard a paper which has stirred me as much as this one, but there are three points to which I would like to refer: In the first place, the case presented is very interesting, and certainly demonstrates the author's skill in making the diagnosis and treating the condition. I have seen but one such case. The second point is the condemnation of all prepared foods, in which I fully agree with the author. However, I entirely disagree with him in regard to a third point—that of deprecating the value of Pasteurized and sterilized milk because scurvy may be produced. This is a dangerous doctrine, I think, and I would like to hear the point discussed. Up to 1894 there have been reported but seventy cases of scurvy in infants, and when we recall the fact that many babies are fed on sterilized milk, we ought not to admit this as a cause of scurvy. Looking back over an experience of thirty-five years, part of which was spent in the country, where good milk is to be had, and seeing many children, I can say that there is nothing, not even hydrotherapy, which has given me more satisfaction than the introduction of sterilized milk. Twenty-five years ago, I remember making a record in my mind as to how many babies among my clientele would die of summer complaint during the coming hot weather; and I could find no preventative, because we did not then know that the cause of summer diarrhea is the bacterium lactis. We know now what it is and how to destroy it—by boiling the milk. In regard to the modification of milk, my views are these—that it does not make so much difference how you modify it, it will agree with the child if you destroy the bacterium lactis. In order to prove this fact, Eserich some ten years ago gave a baby four weeks old a quart of sterilized milk; he then examined the feces, and found that nearly all the nitrogen had been utilized. This proves that infants are capable of digesting ordinary milk without modification. The great point in infant-feeding is to make cow's milk like mother's milk. The latter is superior because it is always *sterile* and is received in the child's mouth direct from the mother's nipple; therefore, cow's milk must be made sterile. Good milk should be obtained from cows which are kept in a clean stable, where every precaution is taken to keep the milk pure, and it should be sent to the laboratory to be made perfectly sterile before it is used. The grade of the milk is not of so much importance if only it be *sterile*.

DR. J. H. FRUITNIGHT: In 1894 I wrote a paper on scurvy, and at that time was able to find but seventy recorded cases of the disease occurring in infants. Up to the present time I have seen but ten such cases, and in all but one the child had been fed on prepared foods. In the one exception the mother's milk had evidently not been sufficiently nutritious, and the baby was put on modified milk and antiscorbutic treatment. One of the cases occurred in a baby two or three months old, whose mother had phthisis and had been obliged to wean it. It was given several of the prepared foods and soon developed scurvy. It presented a terrible appearance; it was covered with ecchymotic spots, the knee-joints were swollen, the gums spongy, and the whole body so sensitive that the slightest touch gave pain, and it was necessary to carry it about on a pillow. It recovered under the treatment detailed by the author. This case is one of the most severe ever recorded and was clearly due to artificial food. A microscopic examination of the blood showed marked leucocytosis. The diagnosis in these cases generally lies between scorbutis and acute rheumatism, for which it is frequently mistaken. The condition was formerly called acute rickets, and is due to faulty nutrition, which leads to a deviation from the normal composition of the blood. Occasionally, a case is reported due to sterilized milk, but the latter should not be condemed for that reason. Prepared foods are much more apt to be the cause. Pasteurized is to be preferred to sterilized milk because it is not raised to so high a temperature as is necessary in the preparation of the latter. The prognosis is nearly always favorable under proper treatment, and if this is faithfully carried out the mortality will be reduced to nil.

In regard to infant-feeding in general, all men who do much work among children condemn the proprietary foods and agree that mother's milk is the best food. Cow's milk is next best. Pasteurized milk has saved many children, and it will be a retrograde step if we discard it. Mere sterilization, however, is not sufficient; it must be *modified* to suit the cases—some babies require more fat, others more casein, and so on. As it requires some thought to prescribe the proper formula for modified milk, artificial foods are often ordered because it is easier to do so.

DR. DESSAU: I have seen but two cases of scurvy and both occurred in children fed on proprietary foods, but it is a question whether this food *per se* was a factor in causing the disease. In regard to the feeding of healthy children, I agree with those who recommend Pasteurized milk for summer feeding. I have used other elements added to the milk, and have come to the conclusion that the best food for infants, rich and poor, is a kind of Pasteurized milk which anybody can prepare. In the first place, good, clean milk must be obtained. This is not always easy, for I am told that since separators have come into general use in dairies, milk from which the cream has been thus separated is sold, and a great deal of it used by the condensed-milk companies,

and, of course, such milk contains hardly any fat. Having obtained a good milk, dilute it one-quarter with water (more or less if the child does not thrive), add a little cane sugar and a pinch of salt, and place this mixture in a double boiler, allowing it to cook ten minutes after the water in the lower vessel has begun to boil. A double boiler can be bought for 35 cents, and is within the reach of even poor people. Children generally thrive on this mixture.

DR. H. LING TAYLOR: I saw one of the cases referred to by the last speaker; that of a child brought up on a certain brand of condensed milk. It is interesting to note that two other children in the same house were fed on this same kind of condensed milk and developed the same symptoms as the child first mentioned, and one of them finally died. A third child living in the neighborhood, also fed on the same food, was affected in the same way as the others. The reason why scurvy in infants is not more often recognized is because there are no stomach or bowel symptoms. This fact leads the physician astray. In my case the diet was changed to Pasteurized milk, and the child recovered. It was also given beef- and orange-juice. There has been of late a decided reaction against sterilized milk. If good milk can be obtained, give it to the child raw, except in hot weather, when some kind of sterilization must be resorted to. Another thing in connection with scurvy is that the child may appear to be perfectly healthy, and even robust, while it is beginning to develop this condition. The infant foods are only indicated when starvation diet is necessary.

DR. ROBERT A. MURRAY: The different expressions of opinion by the members are rather confusing. I consider that Dr. Dessau, by his method, does Pasteurize the milk. In regard to modified milk, it is a fact that mother's milk a few days after delivery is practically the same as it is at the end of lactation. The essential point seems to me is to make a milk as nearly like mother's milk as possible, and to keep it free from germs. Milk must be sterilized, and, whatever method we employ, the same thing is accomplished in the end—it is modified by adding water, salt, and sugar.

DR. JACOBUS: In the first place, I wish to say that, as stated in the paper, I referred to scurvy and not to infant-feeding in summer diarrhea. I limited my remarks to feeding in scurvy and in healthy children. In regard to the statement made by a previous speaker that there are recorded but seventy cases of scurvy in infants, I would like to ask how many thousand cases of this disorder have occurred unrecognized, and progressed, in many instances, to a fatal termination. I also wish to take exception to the statement that mother's milk is always sterile. Laboratory tests show that this is not the case. During the nursing period, a woman's nipple, by reason of the saliva, dirt, and sour milk which collect there, is often a perfect hot-bed of bacteria. Of course, this can be remedied by cleanliness. I have even seen a case of scurvy in a baby which was breast-fed, and in which the disease was due to the poor quality of the milk. In closing, I can only say that for infant-feeding I prefer *raw*, pure, rich milk, the best to be had, which has been filtered after the method of Seibert and modified as suggested in the paper. In addition to this, after the fourth to sixth month, the artificially fed infant should be given beef- and fruit-juice, baked ripe potatoes, with milk, butter and salt, crackers, and other suitable, easily digested foods in small portions at least twice daily.

ANNOUNCEMENT.

MEDICAL SOCIETY OF THE STATE OF NEW YORK; PRELIMINARY PROGRAM, NINETY-SECOND ANNUAL MEETING.

Albany, January 25, 26, and 27, 1898.

TUESDAY MORNING SESSION, 9.15 O'CLOCK.

PRESIDENT'S inaugural address. Reports of officers and committees. Executive business.

PAPERS.

1. "Throat and Nose Affections and Their Relations to General Medicine." Walter F. Chappell, New York.

2. "Ear Manifestations in General Disease." Wendell C. Phillips, New York.

3. "Cases of Acute Non-diphtheritic Inflammation of the Larynx, Requiring the Prolonged Retention of the Intubation Tube." John O. Roe, Rochester.

4. "The Report of a Case of Unusual Contraction of the Visual Field and Disorder of the Color Sense Following an Injury." T. F. C. Van Allen, Albany.

5. "The Railway Surgeon and His Work." C. B. Herrick, Troy.

6. "What Shall the State and County Do for the Consumptive?" John H. Pryor, Buffalo.

7. "The Advantages of State Control in Medicine, with Results Observed." William Warren Potter, Buffalo.

Election, by districts, of members of the Committee of Nomination at close of morning session.

TUESDAY AFTERNOON SESSION, 2.15 O'CLOCK.

8. "A Contribution to the Study of Melancholia, with a Report of the Examination of the Blood in Fifty-seven Cases." B. C. Loveland, Clifton Springs.

9. "The Cold-water Treatment of Typhoid Fever in Private Practice." John T. Wheeler, Chatham.

10. "Anemia." R. C. M. Page, New York.

11. "On the Vagaries and Wanderings of Gall-stones, with Clinical Reports." Henry L. Elsner, Syracuse.

12. "The Treatment of Delirium." Joseph Collins, New York.

13. "Paralysis; Prognosis and Treatment." Edward D. Fisher, New York.

14. "The Relation of Bacteria to the Normal Alimentary Canal." Herbert U. Williams, Buffalo.

15. "The Rivals of the Physician in Practice." Reynold W. Wilcox, New York.

16. "The Hygienic Management of Dairies." E. F. Brush, Mt. Vernon.

17. "The Municipal Control of Milk-supply in Cities and Villages, with Report of Health Regulation." T. B. Carpenter, Buffalo.

18. "The Present Status of Expert Medical Testimony." Evarts M. Morrell, Yonkers.

19. "Expert Testimony." J. B. Ransom, Dannemora.

TUESDAY EVENING SESSION, 7.15 O'CLOCK.

"Practical Exposition of the X-ray in Medicine and Surgery." Exhibition in charge of Arthur L. Fisk of New York. (*a*) "Technic and Apparatus." Samuel Lloyd, New York. (*b*) "The X-ray in Medicine." Dr. Williams, Boston. (*c*) "The X-ray in Surgery." Arthur L. Fisk, New York. (*d*) "The X-ray; Clinical Experiences." Wm. Hailes, Jr., Albany.

WEDNESDAY MORNING SESSION, 9.15 O'CLOCK.

20. "Some Points in the Technic of the Alexander Operation." Herman E. Hayd, Buffalo.

21. "The Present Status of Vaginal Operations for Diseases of the Pelvic Organs." Edward B. Cragin, New York.

22. "Remote Consequences of Excessive Uterine Hemorrhage." W. E. Ford, Utica.

23. "Gauze Drainage in Laparotomy." Henry C. Coe, New York.

24. "The Anatomy and Function of the Female Perineum and the Operation for Its Repair When Lacerated." J. Riddle Goffe, New York.

25. "Traumatic Injuries of the Brain." J. H. Glass, Utica.

26. "Formaldehyd Disinfection." E. H. Wilson, Brooklyn. Discussed by Alvah H. Doty and Herman M. Biggs.

27. "The Past, Present, and Prospective Methods of Treatment of Insanity in the State of New York." P. M. Wise, Albany.

WEDNESDAY AFTERNOON SESSION, 2.15 O'CLOCK.

28. "A Year's Work in Appendicitis." Herman Mynter, Buffalo.

29. "The Management of Undescended Testicle in Hernia Operations." William B. DeGarmo, New York.

30. "Investigation and Exploration of the Other Kidney in Contemplated Nephrectomy." Geo. M. Edebohls, New York.

31. "Congenital Dislocation of the Shoulder Backward, with a Report of Seven Cases and an Operation for Its Relief." A. M. Phelps, New York.

32. Discussion—"The Management of Hypertrophy of the Prostate Gland and Its Complications." (*a*) "General Consideration and Catheter Life." L. Bolton Bangs, New York. (*b*) "Prostatectomy and Prostatotomy, Suprapubic and Perineal." Samuel Alexander, New York. (*c*) "Bottini's Galvanocaustic Radical Treatment, and the Palliative Treatment for Hypertrophy of the Prostate." Willy Meyer, New York. (*d*) "Castration for the Relief of Hypertrophied Prostate." L. S. Pilcher, New York. (*e*) "Stone, Associated with Hypertrophy of the Prostate." E. L. Keyes, New York.

33. "Excision of the Fibula for Sarcoma." Samuel Lloyd, New York.

34. "The Treatment of the Fracture of the Femur in Children." Theodore Dunham, New York.

WEDNESDAY EVENING SESSION.

In the Senate Chamber at 7.45 o'clock. Anniversary address by the President. Reception by the President to the members, delegates, and invited guests at the Albany Club at 9.30 o'clock.

THURSDAY MORNING SESSION, 9.30 O'CLOCK.

Business session and reports of committees.

35. "Treatment of 'Deficient Excretion from Kidneys not Organically Diseased, and Some of the Diseases Peculiar to Women,' and Diseases of the Skin." L. Duncan Bulkley, New York.

36. "The Relations of the Physician to the Practice of Midwifery." C. F. Timmerman, Amsterdam.

37. "The Conservative Surgery of the Fibroid Tumor." A. H. Goelet, New York.

38. "Report of a Case of Osteotomy of Both Tibiæ and Fibulæ for Symmetrical Anteroposterior Angular Deformity." F. H. Peck, Utica.

39. "Intratracheal Injections for Diseases of the Bronchial Tubes and Lungs." H. S. Drayton, New York.

SENECA D. POWELL, New York, President,
LUCIEN HOWE, Buffalo, Vice-President,
FREDERIC C. CURTIS, Albany, Secretary,
CHARLES H. PORTER, Albany, Treasurer.

THERAPEUTIC HINTS.

To Remove Silver Nitrate Stains.—

℞ Hydrarg. bichlor. } aa . . . 3 i
Ammon. chlorid. }
Aq. dest. . . . . ℥ i.

M. Sig. Apply by means of a cloth and friction.

In Infantile Colic.—

℞ Tr. lobeliæ . . . . . gtt. i
Aq. dest. . . . . ℥ i.

M. Sig. One-half teaspoonful when indicated.

For Baldness of Parasitic Origin.—

℞ Pilocarpini . . . . . Parts iv
Sulphuris præcip. . . . Parts x
Balsam. Peru. . . . . Parts xx
Beef marrow . . . . . Parts c.

M. Sig. External use.—*Sabauraud.*

For Fetid Diarrhea in the Initial Stage of Scarlatina.—

℞ Mag. sulph. } aa . . . . . 3 ss
Ac. sulph. dil. }
Syr. simpl. . . . . ℥ ss
Aq. dest. . . . . ℥ iii.

M. Sig. One teaspoonful to one tablespoonful every hour according to the age of the child.

For Scabies.—

Adipis . . . . . ℥ iss.

M. Ft. Ungt. Sig. Rub into affected areas once daily for three days. Woolen undergarments should be worn during the treatment.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXII. NEW YORK, SATURDAY, JANUARY 22, 1898. NO. 4.

ORIGINAL ARTICLES.

NIL NOCERE, IN OBSTETRICS.

BY JULIUS ROSENBERG, M.D.,
OF NEW YORK.

IN consideration of the fact that ninety-five per cent. of all confinements terminate normally and never require medical aid, this axiom, *nil nocere*, is of special significance in the practice of obstetrics. Labor is, as a rule, a physiologic act, and yet this normal phenomenon is not infrequently transformed into a pathologic process by excessive zeal and a desire to do something.

Puerperal infection stands foremost among the complications of childbirth which are artificially produced. Although the mortality from this dread affection has been much decreased, still we observe its clinical manifestations all too frequently. It is my belief that puerperal infection is an absolutely avoidable sequel of labor, and that women need not die or suffer from it, regardless of their immediate environment.

Previous to 1847 the mortality from puerperal infection in the Vienna General Hospital was more than ten per cent. In May, 1847, Semmelweiss established the rule that students, before taking charge of a labor, should wash their hands in chlorin water; he also restricted the number of digital examinations. The result was an immediate fall in the death-rate. Within six months it dropped from 10 to 3 per cent., and in the second year of the new régime it did not exceed 1.5 per cent. To my mind this brief recapitulation of Semmelweiss' work absolutely indicates the etiology of puerperal infection. A woman is practically aseptic until contaminated by the infected examining finger. The simple washing of the hands in chlorin water reduced the mortality from 10 to a little over 1 per cent., and it is but rational to conclude that if the hands had been thoroughly cleansed the death-rate from this affection would have been reduced to nil. Unfortunately for womankind this conclusion has not been universally accepted; thus, many consider the disinfection of the obstetrician's hands without a more or less thorough vaginal douching insufficient antisepsis. This idea originated through the fact that even after disinfection of the hands women continued to die from puerperal infection; but instead of tracing this to imperfection in the preparation of the hands, the vagina was accused of containing the disease-germs.

It cannot be denied that the vagina of every woman contains numerous micro-organisms, but these are, as a rule, non-pathogenic and not responsible for infection, and, what is more, they prevent subsequent sepsis; and by removing them and the normal vaginal secretions we are inviting instead of guarding against infection.

König[1] demonstrated that not only is the normal vaginal secretion free from pathogenic germs, but he has shown that it has a distinct germicidal power. Experiments were made by introducing different germs into the vaginæ of a great number of pregnant women. It was found that all pathogenic bacteria were destroyed within two days after introduction. He further proved that syringing the vagina with antiseptic solutions has the effect of reducing or completely destroying its germicidal power. Hence, he concluded that prophylactic syringing should be abandoned.

During 1894 Menge published an account of researches as to the bactericidal properties of the vaginal secretion, and his results are identical with those of König. Further investigation of the mechanism of this germicidal action shows that it depends mainly upon the antagonism between the normal bacilli of the vagina and the pathogenic micro-organisms (the presence of which is accidental), and upon the acid reaction of the vaginal secretions. These theoretic deductions and investigations are well substantiated by practical results:

In 1893 Leopold and Goldberg published the statistics of several thousand confinements with and without the employment of vaginal disinfection. Their tables show the best results when vaginal douches were omitted. Fischel, in 880 births at the Prague Maternity Hospital, lost nine women from puerperal sepsis with the employment of preliminary disinfection. After stopping the irrigations he delivered 521 women without a death. Neumann reports 700 cases without the employment of vaginal douches and without a single death from sepsis. Frommel reports 500 cases in which vaginal douching with a solution of bichlorid of mercury was employed, with two deaths from sepsis.

I have delivered during the past four years a fair number of women living under the most varying

[1] *Deutsche med. Wochensch.*, No. 43, 1894.

conditions; I never employ vaginal douches except under strict indications, and every one of my cases have recovered without any complications. I have also, during the same period, seen quite a few cases of puerperal fever, and, though it may have been only incidental, in the virulent types a history of prophylactic vaginal and uterine douching was presented. The restriction of vaginal examinations, thorough disinfection of the external genitals of the parturient woman, and an aseptic condition of the examiner's hands are, to my mind, the only essential requirements for the successful management of a normal labor; whatever is added constitutes an unnecessary interference.

The second subject to which I desire to direct attention is the complication of pregnancy and labor by uterine fibroids. I have observed during the last four years six cases of fibroid of the pregnant uterus; four are reported in detail in the *American Journal of Obstetrics*, May, 1895. In five of these cases pregnancy and labor terminated without serious complications; one woman aborted during the fourth month. The growths ranged in size from that of a lemon to colossal tumors. I record *six living mothers* and *five living children*. These statistics are far superior to those offered by the advocates of operative interference. Leopold[1] collected thirty-one myomectomies during pregnancy, with a maternal mortality of twenty-three per cent., while forty-five per cent. of the children perished. Such varying results should lead one to ask whether myomectomy during pregnancy is ever indicated. As for myself, I consider it entirely unjustifiable, and, with but few exceptions, these cases should be left alone until labor has commenced.

The few cases which I have observed prove that even large tumors may cause but slight complications, and I find not a small number of cases reported in which seemingly insurmountable obstacles disappeared during labor and did not interfere with a normal delivery. Some operators justify operative interference by the plea that the operation relieves the woman of the tumor. Against this I have to reply that the structure of fibromyomata closely resembles that of the uterus, and that they partake in the evolution and involution of this organ. Growths which may be of alarming size during pregnancy become, *post-partum*, utterly insignificant, and may never cause the woman any discomfort. If they should do so, then it is time enough to resort to operative procedures.

Fortunately, the current opinion seems to be against operating in these cases. Hofmeier advises strongly against operative interference. His conclusions are that "the presence of myomata during pregnancy, labor, and the puerperium is rarely the cause of serious consequences, and the dangers may be essentially diminished by patience, proper judgment, and an antiseptic management of the case.

Dr. Bantock has observed a large number of cases of pregnancy associated with uterine fibroids, and never had any of the accidents usually ascribed to this condition. He quotes the case of a large fibroid occupying the pregnant uterus in which his opinion was requested as to the advisability of surgical interference. He advised non-interference, in the belief, founded upon experience, that as pregnancy advanced the tumor would rise out of the pelvis and allow the passage of the child; and this was just what occurred. He was present at the delivery, and the labor proceeded perfectly normally. He examined the woman *post-partum*, and had he not known that she had a fibroid, he would have believed the uterus to be normal.

Armstrong has recorded the case of a woman who had a large fibroid. She became pregnant, and was strongly pressed to have an abortion induced, but declined. She had an easy labor. He examined the woman some time later, and found that every trace of the tumor had disappeared.

Routh relates the case of a woman who, when six-months pregnant, was admitted to the hospital. A fibroid the size of a fetal head occupied the lower portion of the uterus, and delivery *per vias naturales* appeared impossible. It was decided to let the woman go to term and then perform Cæsarian section; but one day the tumor rose out of the pelvis, the head descended, and a living child was delivered without difficulty.

To represent the other side of the argument, I shall briefly relate the history of a case, reported by Banza (*Am. Journal of Obstetrics*, April, 1894). A single woman, thirty-six years old, who had always been regular, missed four menstrual periods, and consulted the doctor to ascertain why she was growing so large; she suspected pregnancy. Upon examination, her diagnosis of pregnancy was confirmed; it was also found that the lower portion of the uterus contained several small fibromata. She was told that she was pregnant and that she had a tumor, which, if left until the end of pregnancy, might put her life in danger. Operation for the removal of the tumor, if possible, with preservation of the uterus, was advised. She consented to the operation, uterus and tumors being removed. The patient died of sepsis on the fifth day.

It is a deplorable fact that obstetric text-books preserve a too great reverence for old dicta handed down from book to book. Because some one has

[1] *Am. Journal of Obstetr.*, May, 1895.

witnessed a few fatal results in confinement cases in which myomata were present, although the tumor was generally not the cause of death, we are advised to operate if the tumor gives rise of symptoms. Many operations are reported in which the tumor was the sole indication. But should a procedure which has a mortality of twenty-five per cent. be undertaken except under most pressing indications?

After a most exhaustive study of the literature, and from my own experience, I cannot verify the statement that fibroid tumors occurring during gestation are the cause of so many alarming complications. The reported deaths have mostly been due to sepsis, and to interfering operations.

Clean hands constitute the best prophylaxis for the former, and a regard for the axiom "*nil nocere*" will make the latter less frequent.

EDIBLE AND POISONOUS FUNGI.

By J. N. BUCKHAM, M.D.,
OF FLINT, MICH.

THE increasing use of fungi as food has led me to investigate their botanic structure, their value as an article of diet, and last and most important, to determine the marks of distinction between the noxious and wholesome varieties.

The fungi are next to the lowest order of plants, and are between the algæ and the lichens. The higher forms of fungi and lichens are now grouped together under the name—fungales. Lichens are a fungous growth parasitic on an algal base. Fungals are thallogens; that is, they are nourished through a thallus, mycelium, or spawn. They are parasitic, and absorb the products of decomposing animal or vegetable matter, and generally grow underground. The edible fungi are known as mushrooms, lichens, puff-balls, and truffles.

The fungi consist of a volva, which is the membrane enveloping the fructifying part of the embryo, a stalk, and of a receptacle or expanded cup, to the under surface of which the cortina or veil is attached, covering the hymenophore or conceptacle. The principal appendages are the gills or lamellæ, and their shape, appearance, color, and changes of color, are all important in determining species.

The lichens consist of a thallus and the reproductive organs borne upon it. The *Cenomyce rangiferina*, or reindeer-lichen of Lapland and other Northern countries, furnishes pasturage for the deer in winter. With *Cetraria Islandica*, or Iceland moss, we are all familiar. The *Umbilicaria vellea*, or rock-tripe, is eaten by hunters in the Arctic regions. *Lecanora esculenta*, a lichen of Asia Minor, is supposed to have been the manna of the Exodus.

The commonest form of edible mushroom is the *Agaricus campestris*, or meadow mushroom. The *Agaricus arvensis*, another but coarser variety, grows wherever cattle graze. The *Agaricus cretaceosus* is an excellent table variety. Other wholesome species are *Agaricus ægeritæ* and *avellanus*, *Lipiota procera*, and *Amanita cæsarea*. Puff-balls should not be picked, but a slice cut off when wanted.

Tuber melanospermum, *Tuber cibarius*, and *Tuber moschata* are varieties of truffle found in France, Italy, and other European countries. Truffles grow underground and give off a peculiar odor, which leads to their detection by dogs and pigs trained to hunt for them. Among the noxious species are *Amanita muscaria*, or fly agaric; this is used in this country and in Europe as a fly poison. It is sometimes eaten by the inhabitants of Northern Asia for its intoxicating effect.

In many parts of the world mushrooms form a very large portion of the food of the inhabitants, and in many countries of Europe and Asia they are cultivated on a large scale. In Terra del Fuego they are the chief food of the natives. In France, Italy, New Zealand, Tahiti, and Japan they are an important article of export, and are under government control and inspection. Rollrausch and Ziegel state that they deserve to be placed with meat as sources of nitrogenous nutriment. One man in Thuringia is said by Dr. Gautier to have lived upon nothing but mushrooms for thirty years, and died a centenarian. Dried morel has been found to contain thirty-five per cent. of protein, and *Hellvella esculenta* twenty-six per cent. Different foods contain the following averages of protein substances: bread, eight per cent.; oatmeal, ten per cent.; barley meal, six per cent.; potatoes, five per cent.; beans and peas, twenty-seven per cent., and mushrooms thirty-three per cent.

Many popular fallacies exist concerning certain tests for determining the noxious or wholesome qualities of fungals. One old one is that poisonous varieties will discolor a silver spoon or white onions during cooking. All kinds are liable to liberate H_2S in process of cooking or of decay, and this, of course, will discolor silver, brass, lead, or onions. Another is that all varieties which turn black on being sprinkled with salt are poisonous, and those which do not are wholesome. Other tests are, that all which change color when cut, or have vivid colors or viscid caps are poisonous. These distinctions are not to be depended upon, nor are the contrary hypotheses. It is best to avoid all fungi growing in filthy places, those with an unpleasant odor, those which produce a biting or burning sensation in the mouth, those which yield a white milk, or turn blue or greenish when broken, or those in which the flesh is soft, deliques-

cent, spongy, hard, corky, or maggoty. The amanitas are nearly all dangerous, and some are *very* poisonous, their active principle being amanitine which acts like morphin; eating them does not produce any symptom for six or eight hours, and then the patient is usually beyond help unless sulphate of atropia, $\frac{1}{60}$-grain, is at once administered. All of these have cups, and all fungi with cups had best be avoided.

In edible varieties the flesh is usually firm, but tender, and the odor and taste pleasant and agreeable, resembling fresh meal or hazelnuts. Many of the wholesome kinds are dangerous when old or over-mature, and some of the noxious ones become wholesome when properly cooked. Cases have occurred in which unpleasant or serious results have followed from eating well-known esculent fungi; such may have been due to idiosyncrasies of the victim or simply to overeating. I have thought it possible that ptomains might be developed under favorable conditions; this and the comparative indigestibility of fungi should be investigated more fully than has been done. The only *sure* test of wholesomeness is the hackneyed one of eating them first and letting the result be determined by your own after-consciousness, or appear in your obituary.

THE GOUTY AND RHEUMATIC AFFECTIONS OF THE UVEAL TRACT.

By ROBERT SATTLER, M.D.,
OF CINCINNATI, O.

AFFECTIONS of the eye are among the earliest recorded facts in the history of gout. Long before the gouty or rheumatic origin of other ocular lesions was inferred or established affections of the iris were among the recognized complications of gout and rheumatism, being formerly described under the general term "ophthalmia arthritica." More recently, however, the careful study of clinical histories in typical cases has conclusively demonstrated that, not only in iritic disturbances, but also in certain other lesions of the uveal tract, gout and rheumatism must be considered as among the principal etiologic factors (relapsing cyclitis, iridochoroiditis, etc.). These ocular diseases are, in most instances, associate manifestations of the maladies in question, and start as such in one or the other part of the uveal tract; less commonly, they appear as complications of pathologic expressions due to the same causes (episcleritis, scleritis migrans, sclerotitis, neuritis optica, neuroretinitis, etc.).

Clinically, both gout and rheumatism are thoroughly understood. But, however unmistakable the expression of local and general gout as well as of rheumatism may be, it must be admitted that the obscure nature of both these maladies, as well as the complete absence of a distinct morbid anatomy, are equally incontrovertible facts. If this holds good of gout and rheumatism as a whole, it applies with especial force to the local manifestations of the general disturbance observed in ocular lesions. At the very outset, in disorders of the uveal tract presumedly of gouty or rheumatic origin, every observer of the clinical phenomena is confronted with the ever vexing questions, "Are gout and rheumatism independent diseases, or are they, as Haig and others assume, different utterances of one and the same malady, or is there such a blending of the two that their *common identity* must be upheld?" Are we to believe with Hutchinson that "gout is but rarely of pure breed and often a complication of rheumatism?" How shall we classify that chronic affection of the joints which, in clinical manifestations at least, strikingly resembles both rheumatism and gout, *viz.*, arthritis deformans? These and other equally perplexing questions suggest themselves to the specialist from time to time.

On the other hand, there are certain facts derived from his own observation, the literature of the subject, and the known experience of fellow-physicians, which serve to guide him in his endeavors to analyze the ocular symptoms and establish their dependence upon and association with the general disease. These personal deductions may not add much that is new, but they may tend to confirm or supplement some of the many points in the history of gouty and rheumatic disturbances of the eye, concerning which imperfect conclusions are entertained.

Can gout or rheumatism be considered the principal etiologic factors in those cases of iritis in which a searching examination fails to disclose that the disturbances of the joints are dependent upon syphilis, gonorrhea, chronic lead intoxication, malaria, anemia, and other alleged or actual constitutional causes?

This has long been admitted. The older literature refers to these lesions of the uveal tract as ophthalmia arthritica, iritis varicosa, arthritica, rheumatica, etc. Von Ammon, von Walther, von Beer, Himly, and others are among the earliest German observers to refer to the frequency and severity of this special variety of iritis, and assign its cause to gout or to rheumatoid arthritis. In England, although rheumatic iritis and its causal relationship with rheumatism is recognized, Mackenzie[1] and others hesitatingly refer to iritis of gouty or arthritic

[1] Mackenzie mentions the fact that in Germany chronic arthritis and gouty affections are common among the poorer classes, especially in wine-growing districts. Before the advent of reliable mydriatics these affections, characterized by insidious onset, were fraught with great risk, one acute attack being almost invariably followed by recurrent fatal complications with loss of sight, etc.

origin, even though it is mentioned, admitted, and described in the text books.

Recently, in Germany and on the Continent, less stress is laid upon these causes as etiologic factors; this is evidenced by the scarcity of the literature on the subject and by the infrequent reference and even the complete absence in most of the text-books of the designation "gouty," arthritic, or rheumatic iritis. On the contrary, in England where formerly much doubt was expressed, especially concerning the gouty or rheumatic origin of certain forms of iritis and choroiditis, opinion has gradually changed. Jonathan Hutchinson was the first to accumulate, by painstaking labor and observation, such a mass of clinical evidence that the gouty and rheumatic origin for these and other affections of the eye can no longer be questioned. Since then it has been known that many cases which were formerly described by the vague term "idiopathic" or were indiscriminately classified as being of rheumatic origin are really expressions of the uric-acid diathesis and belong to the stage of goutiness (a variable period which precedes acute local paroxysms), or again, are evidences of the rheumatoid stage with its common and uncommon manifestations, including many neurasthenic and neuropathic symptoms, oxaluria, intestinal indigestion, eruptive and herpetic lesions of the faucial and other mucous and cutaneous surfaces, and finally terminating in an acute invasion of the larger joints.

If, as it is claimed, 60 to 75 per cent., or even a higher percentage of iritic, ciliary, and choroidal disease is dependent upon constitutional syphilis, acquired or inherited, 5 to 10 per cent. upon toxic and septic causes (lead-intoxication, gonorrhea, etc.), and the remaining portion—15 to 30 per cent.—upon gout and rheumatism, what share of this is assignable to gout, what proportion to rheumatism, and lastly, what portion to the manifestation of disease which is a blending of both and is designated as rheumatic gout?[1]

Mr. Hutchinson assigns an important share to gout as an etiologic factor, but a major share to what has been termed by him and others rheumatic gout. "The more purely a case is one of rheumatism the less is the possibility that iritis will occur. When iritis is present, the complications are almost invariably those which suggest what we call rheumatic gout, rather than rheumatism pure and simple." In this country, with its diverse and changeable climate, mixed population living amid every condition of favorable and unfavorable hygienic surroundings, rheumatic affections are not rare, and it is not uncommon to meet with iritis and other choroidal complications which, on account of their unmistakable resemblance to rheumatism, must be classed with "rheumatic affections."

Under all circumstances it is evident that in a certain number of cases the ocular disturbances mentioned represent a part of the group of symptoms which are an advanced expression of one and the same diathesis; on the one hand, in gout, the presence of uric acid in the blood and deposits of biurate of soda around the small joints constitute the main pathologic alterations; while, on the other hand, in rheumatism—in its acute or chronic form—the characteristic inflammatory invasions of the larger joints are found. Among other deleterious agents, the same morbid product (uric acid) is present, but undergoes different transformation after accumulation in excessive quantities. As a necessary sequence, in both cases, there are enacted peculiar changes which interfere with and pervert the metabolic processes, especially of the connective tissues and lymphatic channels. It follows from this that we may expect iritic and other ocular complications in both of these maladies, and also in that form which is a fusion in both, the so-called rheumatic gout.

At what period are iritic and other lesions of the uveal tract apt to occur? Are they more common during the acute outbreaks of local gout and rheumatism or during the latent periods of these affections?

As a rule, ocular complications appear during the early manifestations of the uric-acid diathesis, or during the stage which precedes for a longer or shorter period acute outbreaks of either gout or rheumatism, or during the intervals of acute or sub-acute recurrent attacks.

In one of my cases a violent rheumatic seizure affecting the larger joints persisted more than a year and finally disappeared without tophaceous deposits or stiffening of the joints. Recently, five years after the first and only attack, the patient developed acute iritis of the right eye after walking over damp grass. After violent suffering and typical objective symptoms the attack rapidly subsided. It was preceded during several months by neurasthenic disturbances, malaise, migraine, etc. In another case, coincident with the clinical picture of so-called serous iridochoroiditis and unmistakable evidences of a uric-acid diathesis, a most persistent disturbance with frequent and violent relapses occurred. Seven years afterward, inflammatory invasions of the joints followed and continued more than a year. During this period the ocular symptoms were quiescent, but after the subsidence of the joint disturbance they recurred with violence. The patient came to me about this

[1] Unquestionably, cases of iritis have been added to this category which occur in the course of that chronic affection of the joints known as arthritis deformans or crippling rheumatism. This disease, on account of its symmetric deformities, etc., is looked upon as a trophoneurosis (allied to the chronic arthropathies met with in chronic affections of the spinal cord), and should not be considered in this classification.

time, and an iridectomy was at once advised and performed, with temporary arrest of the inflammatory activity. Since then repeated recurrences have taken place, and have resulted in a low grade of chronic iridochoroiditis with dense precipitates on the posterior surface of the cornea, but no tendency on the part of the coloboma to become occluded. The ultimate fate of this eye will most probably be its removal to avert uncontrollable inflammatory disturbance and suffering.

The question whether in exceptional cases iritis and choroiditis may be simultaneous expressions and prominent among the other clinical phenomena during an acute outbreak of either gout or rheumatism, has generally been negatively answered, and no reliable clinical data are to be found among the mass of recorded cases in the literature of gout or rheumatism. In fact, it is safe to state that the ocular attack is never simultaneous, although, in exceptional instances, it may be a concomitant expression. If such processes are lighted up during an acute attack, they must rather be considered a coincidence than otherwise. The following observation is interesting because it bears upon this point: A woman, aged fifty years, complained of a persistent burning sensation about the eyelids. Her eyes had the typical "hot eye" appearance so often seen in gouty subjects. A simple collyrium was advised. The following day I was sent for, and found that a violent rheumatic seizure, affecting the shoulders and hips, had occurred with severe pain in both eyes. Examination disclosed marked episcleral injection, aqueous humor discolored, and dusky irides. The interesting feature was that rapid subsidence of the attack followed the administration of salicylates and the application of the usual local treatment.

Do the ocular disturbances, and in particular the lesion under consideration, offer any confirmatory evidences to any one of the many theories advanced to explain the morbid changes which affect the joints, tendons, and fibrous tissues in gout and rheumatism?

It must be at once admitted that there is nothing distinctive in the pathologic appearance of an iritis or iridochoroiditis by which it may be invariably recognized and connected with these constitutional maladies. A part of the entire category of symptoms of the uric-acid diathesis, or the unmistakable gouty or rheumatic cachexiæ, must be present before the ocular lesion can with reasonable certainty be assigned to these causes. Nevertheless, there are certain local features which strongly suggest this origin, even though there may be a lack of evidence as far as the general symptoms are concerned. So far as offering a positive deduction concerning the morbid anatomy of gout, the pathologic process appears to attack principally the lymphatic circulation and the delicate connective-tissue fabric, thus resembling the great connective-tissue disease—syphilis.

As to the question whether it is possible to differentiate between gout and rheumatic affections at any time during the progress of these maladies, and whether the greater share, as an etiologic factor in iritis and other uveal lesions, may be assigned to gout or rheumatism, it may be stated that during the prodromic stages or after a blending (local and general) of the symptoms occurs it is impossible to do so. But during the early stages, before the characteristic alterations have occurred in the joints,—either as the typical gouty or rheumatic affection—as specialists we can establish a more rational etiology in assuming one or the other or both of the general diseases in question as the cause of the lesions affecting the eye.

1. During the stage before gouty or rheumatic invasions of the joints occur, we can scarcely speak of either of these affections as gout or rheumatism *per se*, but they must be regarded as goutiness, so-called, or a rheumatic or rheumatoid tendency.

2. After the malady is declared it may happen that the pure characteristics are preserved a long time, or even become permanent, so that the patient, on the one hand, presents only the typical gouty manifestations, or on the other, only the typical rheumatic evidences, as far as the joints and other general symptoms are concerned.

3. In other cases again, as both progress or develop, one affection partakes more or less of the characteristics of the other, until such an intimate fusion takes place that by common consent the term rheumatic gout has been selected.

The Gouty Affections of the Uveal Tract.—During the stage of goutiness or latent gout, before its declaration as an acute disturbance of the smaller joints, especially of the foot and hand, we meet with annoying complaints, chiefly referable to the constant presence of muscæ volitantes. In most cases, careful examination discloses a normal fundus oculi, with unimpaired sight and function. In addition there may be found a passive congestion of the vessels of the sclera and episcleral region, the typical "hot eye" of the English. The ocular may only be part of other neurasthenic disturbances, or of an overwrought state of the nervous system; but not infrequently the muscæ volitantes have a pathologic importance and are prodromic of exudative choroiditis. A definite pathologic expression of iritis is rare. It is more frequently observed as a complication of scleritis, episcleritis, and disseminated sclerochoroiditis, as the following cases show:

CASE I. *Sclerotitis or Sclerocyclitis Migrans, Complicated with Iritis.*—Miss B., aged twenty years, a

large, over-developed young woman, weighing about 200 pounds. Tophaceous deposits in the hands. Has had several violent attacks (3) in left eye, always accompanied by iritis. During the early stages of relapse activity seems to be concentrated in the sclera and episcleral tissues. Typical "hot-eye" appearance is also present. The last attack occurred in January, 1897; the new feature was an infiltration around the insertion of the internal rectus muscle, with severe complaint when an attempt was made to move the eye to the right. The attack lasted longer than the former ones, but recovery finally occurred.

A far more frequent lesion is an insidious variety of exudative choroiditis (Case II.) which appears under the clinical picture of so-called serous iritis or iridochoroiditis, usually occuring during the initial stage of gout or during the intervals between acute attacks.

CASE II. *Serous Iridochoroiditis and Exudative Choroiditis.*—The disease of the choroid began when the patient was nineteen years old. At the age of thirty-four years complicating cataract, preceded by increasing vitreous opacities, hemorrhages into the choroid, etc., with total abolition of function resulted. Seven or eight years after the ocular lesion manifested itself, evidences of goutiness appeared, and since then he has had repeated typical expressions of local gout. The family history in this case conclusively suggests gout, the father had rheumatic gout, and of a family of four, two, both sons, have had declared gout, a daughter has had goutiness, and the oldest son has also had gouty manifestations in the eyes in the form of persistent muscæ volitantes with unimpaired function.

Of all the obscure ocular lesions caused by an outbreak of gout this is the most treacherous. Muscæ volitantes, functional disturbances of vision, subjective "glimmering," luminous appearances, etc., are present for months, when the so-called "iritis serosa" is added. The disease causes seroplastic exudation into the anterior chamber and on the surface of the iris, posterior synechia, floating opacities in the vitreous humor, especially in the anterior portion, and deposits on the posterior lens-capsule. Progressive failure of vision and most annoying subjective disturbances are usually present. In rare cases, the ocular tension may be reduced; far more frequently it is increased, finally terminating in secondary glaucoma.

The local treatment requires the utmost care and discrimination. Mydriatics and myotics are dangerous, and cocain is useless. Benefit may result from the application of moist heat or hot irrigation to the closed lids. Paracentesis of the anterior chamber, repeated daily according to indications, is in many cases a beneficial measure. If in spite of this the tension remains increased, an iridectomy or a sclerotomy may become necessary. Active internal medication by means of colchicum, salicylates, etc., hot baths, together with local application of moist heat, supplemented by paracentesis corneæ, and the cautious use of either myotics or mydriatics in weak solutions, according to indications, may alone avert enucleation. Nevertheless, in many cases removal of the eye finally becomes the only measure of expediency to rid the patient of an interminable and incurable affection. In the more favorable cases recovery ensues with impairment of vision; in others, one or several scotomata are left, especially if the goutiness develops into declared gout. This is almost the rule, and if a persistent, chronic, degenerative process affecting the entire uveal tract is excited, the disease terminates with atresia pupillæ, cataracta complicata, etc.

This lesion of the uveal tract is, in my experience, the most frequent expression of the gouty diathesis. It is as obscure as the nature of gout itself. It manifests itself as a serous or seroplastic inflammation of low grade, accompanied by chemic changes in the composition and quality of the aqueous humor. The alterations in the anterior chamber and iris only mask the real lesion, which consists of single or multiple exudates into the choroid near the equator, or in the anterior part of the choroid and ciliary body.

Another less frequent lesion is iritis, associated with zona ophthalmica, or herpes zoster of the eye. This may occur in gouty subjects, especially males with inherited gout, or as an expression of advanced "goutiness," or during the intervals of declared gout. It is important to differentiate between iritis which is primary and that which is secondary to the eruption of herpetic vesicles on the cornea, and along the course of the frontal divisions of the ophthalmic branches of the trigeminus. Two of the cases reported below illustrate the more infrequent primary iritis, and the third shows the more frequent form in which the iritis is secondary to the primarily affected cornea.

CASE III. *Zona Ophthalmica—Iritis Plastica.*—E. S., aged sixty-nine years, family history unmistakably gouty. He has two brothers, one of whom had rheumatic gout, the other rheumatism. Patient has tophaceous deposits and gives a history of subacute gouty disturbances. Coincident with the herpetic eruption (brow), violent iritis plastica occurred, but no herpes vesicles on the cornea or conjunctiva. Subsidence of attack took place after six weeks. Disturbance of vision and floating opacities first noticed February, 1896. There was a recurrence of the choroidal trouble, and greater impairment of vision. January, 1897, a more violent attack occurred, accompanied for the first time by severe pain and hemorrhagic iritis. Repeated paracentesis of the anterior chamber was resorted to, in conjunction with absolute rest, use of hot applications, and the

internal administration of colchicum, salicylates, etc. There was little or no improvement in vision, no synechiæ, but gouty manifestations continued.

CASE IV. *Zona Ophthalmica—Irits Plastica.*—A. K., aged sixty-seven years, had a neuralgic seizure and typical eruption of herpes following the course of the frontal and lachrymal branches of the right trigeminus. Iritis commenced when this subsided; the suffering returned, but was not as violent as that accompanying the herpes vesicles. He is at present under treatment. No adhesions, but deep and typical herpes scars in skin of brow and scalp.

CASE V. *Zoster Ophthalmicum—Kerato-iritis.*—Mrs. McC., presented typical local and constitutional symptoms of herpes zoster; eye trouble was coincident with eruptive stage; suffering intense. Family history conclusively demonstrated a gouty tendency. Patient has tophi and unmistakable evidences of goutiness, but has never had declared gout.

Another rare expression of the gouty diathesis appears under the guise of a low grade of iritis, or of the iridochoroiditis referred to, the process being secondary to degenerative changes which affect the retina, and finally resulting in glaucoma. Iridectomy, in such cases, although indicated, is fraught with danger.

CASE VI. *Chronic Iridochoroiditis Plastica—Synechiæ Posteriores.*—Mrs. H., had rheumatism twenty-two years ago. Insidious chronic iritis commenced ten years ago; numerous exacerbations. In spite of local and general treatment, double iridectomy, etc., the degenerative process continued. Recently, patient has had fresh exudative choroiditis in best (right) eye, attended by all the local symptoms of the so-called "serous" affection.

Equally rare are those cases, also unquestionably of gouty origin, manifesting themselves during the later periods of chronic glaucoma (frequently unilateral), in which the most experienced surgeons as a measure of rational empiricism would first propose an iridectomy rather than immediate enucleation. The inevitable prognosis in such complicated lesions may be inferred from the brief history of the two cases which follow. Severe hemorrhage from the retinal and choroidal arteries, followed by the almost instantaneous extrusion of the contents of the globe, is rather a depressing experience, but one that many have encountered, and which has been reported in some instances, and perhaps left unrecorded in a larger number:

CASE VII. *Chronic Inflammatory Glaucoma.*—Mrs. G., aged sixty-nine years; vision gradually lost after repeated subacute inflammatory exacerbations of glaucoma. T : : No. I. General appearance of eye, with the exception of the glaucomatous changes, favorable. Patient being adverse to enucleation, an iridectomy was substitued, and instantaneously followed by complete extrusion of the contents of the globe through the incision; incision closed by sutures, and globe at once enucleated. The patient was a gouty subject, as tophi and history disclosed.

CASE VIII. *Chronic Glaucoma.*—H. B., aged seventy years, presented evidence of rheumatic gout. Left eye has been blind and painful several months. Although the eye's appearance did not suggest degenerated blood-vessels, enucleation was nevertheless advised as the safest plan. The patient being adverse to this, decided to have iridectomy performed first. This was done, and was immediately followed by hemorrhage and extrusion of the vitreous humor, of course, necessitating enucleation.

I also wish to refer to the gouty diathesis as one of the causes of glaucoma. The subject is of such interest, and requires such extensive consideration, that it is impossible to make more than a passing reference here to the fact that among the alleged causes of glaucoma, the source and origin is placed in the iris angle and lymphatic spaces of this locality. In this connection the condensed history of two cases is given, both women, with double non-inflammatory glaucoma:

CASE IX.—An iridectomy, with large, key-hole-shaped opening, was performed on both eyes. For months before the operation the disease was kept under control by the use of eserine, and on account of the controlling effect of the myotic and the favorable appearance of the external structures an operation for permanent relief was undertaken. Operative interference resulted disastrously, a chronic iritis or iridochoroiditis, doubtless due to miliary hemorrhages in the retina and choroid, hopelessly destroyed the sight of both eyes.

CASE X.—Patient is at present under observation. A double iridectomy, clean and smooth, was followed within eight weeks by a low grade of iridochoroiditis in both eyes, resulting in complete abolition of sight in the right eye and with a fragment of vision remaining in the left.

I believe that in both these cases a gouty origin was responsible for the glaucoma, and directly for the disastrous complication, although no general manifestations of gout were present, either immediately before or after the operation. I believe that these cases are identical with those unfortunate experiences (fortunately rare) which some oculists have had after an operation for the extraction of mature cataract, which, from all external indications, functional tests, etc., promised favorable results, and which, regarding the operation as such, was smooth and uncomplicated. During the operation or immediately afterward successive hemorrhages occur in the retina, choroid, and vitreous, without exciting any active disturbance. The healing of the wound is uncomplicated, and there is no visible unfavorable reaction, but when finally the sight is

tested, vision is found to be nil. Several years ago an experience like this happened to me in a case of "rheumatic gout." Uncomplicated extraction of cataract was followed by uneventful healing. Eight days later, after insisting that the patient must be able to count fingers, an assertion which she persistently denied, I was at last convinced of the truth of her statements when ophthalmoscopic examination disclosed the vitreous full of hemorrhages, and retina and choroid detached.

In concluding this part of the subject, the history of a case is given which, as far as my experience is concerned, is exceptional:

CASE XI.—Mrs. McM., aged forty-seven years, was attacked during the night with excruciating pain in the left eye. This continued several hours, attended by profuse weeping, photophobia, but especially great suffering when she attempted to move the eye.

I saw the patient on the following day in consultation. I learned that she had just passed the menopause amid great strain and suffering. She was a confirmed neuralgic; had had herpes zoster, eczema, and migraine. In fact, she showed every evidence of the so-called uric-acid diathesis, but no frankly declared gout or rheumatic disturbance. The history of a former eye trouble was absent, and from her account my first impression was that she had acute glaucoma.

The examination, however, revealed a different state of affairs. The lids were glossy and tense. The ocular conjunctiva was intensely congested and chemotic; the sclera, bluish gray, aqueous, discolored; the pupil, contracted and sluggish; iris, dull; globe, exophthalmic, with an appearance resembling incipient panophthalmitis; motion of the globe visibly constricted in every direction and excessively painful. She complained of nausea on attempting to open the eye; tension, unchanged; moderate dilatation of pupil after a drop of atropin solution. Ophthalmoscopic examination disclosed precipitates on anterior capsule of lens and posterior surface of cornea, and exceptionally pronounced optic neuritis, with enormous swelling and edematous infiltration of the adjacent retina.

During the following days, amid recurrences of suffering which in character resembled gout, on account of the exquisite sensitiveness of the lids and the attendant constitutional symptoms, the globe became almost immobile and moderate proptosis continued several days.

By the use of anodynes, absolute rest, leeches, and atropin, the iritis and swelling of the external parts subsided within eight or ten days, but any atttempt to move the globe was attended by pain during many weeks. The optic neuritis slowly subsided, and complete restoration of sight finally resulted. The patient was recently seen, and has had no recurrence.

It may be asked was this an attack of acute iritis in a gouty subject with optic neuritis—a complication which is not uncommon? Was it angioneurotic, or a sudden vasomotor paralysis of the tissues of the orbit? Was it a sudden obstruction in the lymph-channels in the cavernous sinus, or was it a local expression of gout?

Gout is infrequent among women, even though "goutiness" is not. It is admitted that these disturbances are more frequently met with after the menopause.

The Rheumatic Affections of the Uveal Tract.—We not infrequently observe lesions of the uveal tract in regard to which a distinct history is obtained which suggests either a rheumatic tendency without acute disturbances of the joints, or positive inference that one or several paroxysms of declared rheumatic seizures preceded the ocular disturbance. Such manifestations, in character resembling those seen during the stage of goutiness, may precede or follow the active local rheumatic invasions of the larger joints, and we are almost constrained to admit their rheumatic origin.

If such active paroxysms assume all the other characteristics which force us to assign them to the rheumatic group *per se* before a blending with gout or a rheumatoid arthritis has occurred, we can furthermore determine that it is during the period of unknown duration which precedes the acute local attacks, or during the intervals between recurrent attacks, that lesions of the iris, ciliary body, and choroid are apt to be manifested; just as in gout, ocular disturbances of rheumatic origin rarely or never happen during an acute or subacute rheumatic invasion of the joints.

The designation "rheumatic" has always been a vague one, for evident reasons. There is no marked morbid anatomy; therefore, all conclusions concerning its real nature are based upon speculative knowledge, supported, it is true, by a mass of clinical facts. In the search for a rational etiology for these lesions of the iris, when all other known causes have been excluded, it must be assumed, in the absence of more positive proof, that there exists a so-called "rheumatic tendency." Although we do not know exactly what the rheumatic tendency is, we do know, with much more certainty, what it is not.

Goutiness possesses a more or less definite expression. The rheumatic tendency has no end of expressions, because it includes almost every known clinical manifestation. The well-known etiologic dependence of rheumatic seizures upon syphilis, gonorrhea, septic and toxic disturbances, malaria, anemia, etc., demands of every specialist a most stringent examination into the real cause. In this rheumatism differs from gout; with the latter struma, phthisis, herpes zoster, and glycosuria are known to

be only occasionally correlated; however, the former, besides its own clinical peculiarities, is very often the conspicuous local expression of a number of constitutional diseases.

Among the early manifestations of the rheumatic diathesis may be found affections of the uveal tract, and functional derangements of the ciliary muscles, or distressing asthenopic disturbances are observed. The most frequent inflammatory affection of the uveal tract due to this cause is iritis, acute and chronic. In its acute plastic form it may be insidious, and in some cases it is only the most conspicuous expression of a general iridochoroiditis; and in others, less commonly, its onset is sudden, its course more rapid, and its symptoms more violent.

Case XII. *Acute Plastic Iritis.*—Mr. C., married. Iritis came on after overheating and overexertion; severe pains in muscles of lower limbs, with stiffness of joints, developed within six hours. Iritis, coincidently developed in both eyes.

Upon the administration of salicylates, and the use of rest, leeches, and atropin, the attack subsided, without synechiæ, and without implication of the choroid.

Case XIII. *Acute Plastic Iritis.*—Mrs. R., aged twenty-six years, was a strong, healthy woman. She was suddenly attacked with pain in the eye and severe neuralgia. In spite of the most rational treatment, suffering persisted. When I first saw her objective symptoms of iritis were pronounced. Absolute rest in bed, large doses of salicylate of sodium, and vapor baths were resorted to, recovery, without synechiæ, resulting.

Case XIV. *Iritis Plastica.*—F. S., aged sixty years, had had rheumatic manifestations many years, never acute, but frequently disabling him weeks at a time; no tophaceous deposits. Mental worry was an element in the case. A residence along the river bank predisposed him to these attacks, which have occurred with especial frequency during the fall of the year. Both eyes have been affected, but never at the same time.

Another more accentuated expression of plastic iritis is occasionally observed. The onset is sudden, the course stormy, and the suffering intense. Amid local symptoms so violent that at first a parenchymatous or a suppurating variety is suggested, an acute plastic process occurs, and assumes exceptional characteristics. The anterior chamber becomes completely filled with an opalescent grayish-yellow exudate of plastic lymph. As the inflammatory symptoms disappear this yellowish exudate subsides, and generally may be noticed to contract around a central point, which appears agglutinated to the anterior capsule in the middle of the moderately dilated pupil. Another feature of interest is that synechiæ are not as common as one would be led to infer from the apparent severity of the attack. The following cases are typical of this variety of rheumatic iritis:

Case XV. *Acute Plastic Iritis in Both Eyes.*—Dr. P., after a violent acute catarrhal or rheumatic attack, follicular sore throat, muscular soreness, and lumbago, had, after subsidence of these symptoms, a sudden and violent inflammation of both eyes.

The diagnosis was unmistakable, the symptoms being so violent that Dr. S. C. Ayres of Cincinnati saw the case in consultation with me. The usual remedies were resorted to, and paracentesis was also performed. The exudate, however, was tenacious, and the aqueous humor so completely absorbed that nothing escaped. The opalescent mass, through which the pupil could be seen, gradually contracted around a central point at or near the middle of the pupil. The periphery cleared up first, and perfect vision was finally restored.

Case XVI. *Acute Plastic Iritis.*—A. P., aged forty-two years. An exudate into the anterior chamber completely filled it. In addition, there were numerous hemorrhages on the surface of the iris, resulting in a vivid, straw-colored appearance. This contracted around a central point near the middle of the pupil, and disappeared completely. No recurrence has taken place.

The chronic variety either as an expression of general iridochoroiditis or as the result of an acute process, beginning and confining itself to the anterior portion of the uveal tract, is, with all its unfortunate consequences, one of the most dreadful of the lesions of the eye. The following case illustrates the gravity and hopelessness of such disturbances:

Case XVII.—Miss A. B., presented an indefinite family history pointing to a predisposition to rheumatism. During girlhood she had a rheumatic knee-joint followed by permanent deformity; no pain or disturbance since. Two years ago she had plastric iritis which merged into the chronic form, and resulted in atresia pupillæ of both eyes. When she consulted me she refused operation, and when she returned, six months later, the prospects were hopeless, and the operation failed to bring about improvement in vision.

Cyclitis is not uncommon. It is most commonly observed in young girls or during early womanhood. It is generally associated with sclerotitis, or its milder equivalent, episcleritis migrans. The pathologic process of exudative choroiditis, which begins in the choroid and assumes the picture of so-called iridochoroiditis and serous iritis, is not only destructive to vision, but, because a chronic iridochoroiditis is excited with especial liability to hemorrhagic extravisations into these structures, enucleation is frequently rendered necessary, as shown by the following case:

Case XVIII. *Relapsing Cyclitis—Exudative Choroiditis, and Later, Iritis.*—Sister B., aged twenty-

five years. The patient, a delicate woman, had subjective symptoms suggesting exudative choroiditis. This was confirmed by ophthalmoscopic examination. In spite of tonics, alteratives, etc., it became necessary, because of exquisite suffering and hopeless degeneration, to enucleate the eye. Rheumatic disturbances affecting the muscles and the larger joints were persistent and frequent.

Affections of the Uveal Tract Associated with Rheumatic Gout.—It must be held that in this group, which is a blending of gout and rheumatism, lesions of the uveal tract, and iritis in particular, may occur. The iritis does not possess distinctive local characteristics, but because of the typical changes in the joints, the diagnosis of the ocular lesion is almost suggested by the appearance of the patient. My own observations have familiarized me with several typical instances conclusively proving iritis to be one of the complications of this general affection; cyclitis and choroiditis are not so common. Of four cases of which I have preserved brief notes two are mentioned because they all have in common stiffening, tophaceous deposits, and other deformities of the smaller and larger joints, and also hereditary tendency to affections of the joints.

CASE XIX. *Chronic Iritis Plastica.*—A. R., aged sixty-eight years, had exceptionally severe attacks of rheumatic gout affecting the knees and ankles, during which he never had eye trouble. It was during the intervals between the attacks of the general affection that several different times he was led to the office for treatment of the eye trouble. Finally atresia pupillæ resulted, but vision remained exceptionally good. Operative interference was refused.

CASE XX. *Plastic Iritis.*—A. F., aged thirty-six years. Had frequent relapsing attacks during intervals of joint-disturbances; great distortion of articular surfaces.

CLINICAL MEMORANDA.

NOTES ON CASES OF SYPHILIS.

BY JAMES C. JOHNSTON, M.D.,
OF NEW YORK;
DERMATOLOGIST TO THE NEW YORK LYING-IN HOSPITAL; PHYSICIAN TO THE CLASS OF SKIN AND GENITO-URINARY DISEASES IN THE OUT-DOOR DEPARTMENT OF THE PRESBYTERIAN HOSPITAL.

Precocious Gummatous Syphilide. — The patient, a woman aged thirty-five years, acquired her disease, maritally and genitally, during June, 1897. When she presented herself for treatment in September her face was disfigured by the lesions of syphilis. According to her statement, the gummata developed gradually without intermission from the early secondary outbreak. In addition to the face, the tumors were dotted over the upper and lower extremities. They were rounded, almost hemispheric, not scaling nor crusted, and varied in diameter from a quarter to one inch. They projected considerably above the surrounding skin level. As a rule, the color was a deep, purplish-red, shading through stages of regression to pink. They were freely movable over the fascia, and in the case of the newer lesions, under the integument, thus proving their origin in the subcutaneous tissue. No other symptoms of the early period were present with the exception of nocturnal headache and multiple adenopathy.

Ulceration did not occur since involution began shortly after the institution of treatment, which, in order to secure a swift and sure constitutional result, consisted of inunctions with blue ointment. An ounce of the latter was divided into ten equal parts, one of which was vigorously rubbed into the skin ten to fifteen minutes each night. The residue was washed off in the morning. In order to prevent an outbreak of mercurial dermatitis, the site of inunction was rotated as follows: first the right and left chest, then the abdomen, and finally the inside of the thighs. After three weeks of nightly rubbing, a change to every other night was ordered. This routine was continued without a break. At the present writing (December, 1897) only a few scaling spots remain to mark the sites of the gummata.

In using inunctions, care should be taken to select non-hairy parts. It is singular that as a rule women raise so little objection to the application of the ointment, dirty as it undoubtedly is. Whether a haunting fear of the disease or the relief from the mental burden of pill-taking is responsible for this complaisance, is hard to say. In private practice, Dietrich's ointment is preferable to the officinal unguentum hydrargyri, as it has a soap base, seems more readily absorbable, and is certainly more easily removed. Iodid of potassium, in 20-grain doses, three times daily, relieved the headache within a week.

Nephritis During Early Syphilis.—The patient is the husband of the woman whose case has just been described. He is an engineer on an ocean steamship, exposed to much hardship and temptation in the way of dissipation. He was sent to me by his wife September 20, 1897, five months after infection—according to his statement. No trace of cutaneous eruption could be found; a slight scar remained at the site of inoculation, but a diagnosis of active syphilis could be made from the mucous patches in the mouth. His health was completely broken down. A pronounced anemia was present, the hue of the skin resembling that of chlorosis. He complained of headache, cardiac palpitation, and shortness of breath to such an extent as precluded sustained effort. His lower extremities were edematous, and his urine scanty and high-colored. On examination the urine showed a specific gravity of 1028, albumin, and a few epithelial casts. He was placed on a milk diet and mercurial treatment (inunction, as in the case of his wife), but grew worse and, attempting another trip, was invalided home from Havana.

Three weeks from the date of his first visit his powers of assimilation seemed to have failed. In consequence, his appetite was enormous—the bulimia syphilitica described by Fournier. Specific medication was stopped, the milk diet was continued, and a tonic, consisting of the syrup of the iodid of iron with cod-liver oil and hypophosphites,

was administered. A month later, the condition was much improved; the symptoms of nephritis had almost disappeared, and a more liberal diet was permitted. The use of mercurials will be resumed when the general condition warrants specific medication. Fordyce (*Jour. of Cutan. and Genito-Urin. Diseases*, April, 1897), Mauriac, and others have reported similar cases.

Syphilitic Myositis.—The two cases of this manifestation of syphilis of which I have notes possessed almost exactly similar characteristics. Both occurred in young men under thirty years of age, in the early stage of the disease, and in otherwise apparently good health. In both, the middle third of the sternocleidomastoid muscle of the left side was affected. The symptoms were a diffuse swelling in the body of the muscle, stiffness, and slight pain on movement. The myositis is easily differentiated from swelling of underlying lymph-nodes, from rheumatism, by the involvement of a single muscle, the brawny character of the swelling, the presence of other signs of syphilis, and the reaction to medication. It is rather unusual to find syphilitic myositis before the end of the second year of the general disease; both of these cases occurred earlier, and both patients recovered following local and general inunction of gray ointment, used as in the first instance mentioned.

Quite a number of such cases have been reported, and from a study of them it has been determined that the relative order of frequency is (one muscle being usually affected), the gastrocnemius, biceps, sphincter ani, masseter, sternomastoid, and others only exceptionally. Syphilitic muscle inflammation is of two kinds, interstitial and gummatous. Occasionally, a mixed form is observed. In the first, the inflammation spreads diffusely through the endomysium; in the second, there is usually a single node. In either case, a degeneration and absorption of the muscular fibers may result if the process is allowed to continue, the place of the fibers being taken by new connective tissue. In this event, permanent shortening and deformity is, of course, to be expected. Prognosis is good with proper treatment.

A PERSONAL EXPERIENCE IN RENAL SURGERY.

By ROBERT F. WEIR, M.D.,
OF NEW YORK;
PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, AND SURGEON TO THE NEW YORK HOSPITAL;
WITH THE COLLABORATION OF
EDWARD M. FOOTE, M.D.,
OF NEW YORK;
SURGEON TO THE RANDALL'S ISLAND HOSPITALS.

(Continued from page 81.)

RENAL CALCULUS.

Renal Calculus—Nephrolithotomy.—Under this heading are embraced seven cases, all resulting in recovery, although in three the renal damage was so great that nephrectomy was necessary. In five of the seven cases there was an associated abscess in the pelvis of the kidney (pyonephrosis) or in the cortical tissue (pyelonephrosis). The calculi removed were principally composed of calcium oxalate or of phosphates. Only once was a stone composed of uric acid found. The largest calculus weighed 510 grains; the greatest number found in any one case was forty-one.

The Röntgen ray was employed in but one instance, a recent case, with a negative result—an experience which has occurred to many in the early employment of the X-rays. This is partly due to the fact that the calculi composed of uric acid and the urates are easily penetrated by the rays, while the only ones which give a good shadow are those of oxalate of lime, and, to a less degree, the phosphatic calculi. With the later improvements in the tubes and plates better results have recently been obtained, and to this end additional benefit may be derived from the advice given by Myles,[1] based upon anatomic experiments, that the light should pass through the kidney from a point backward and outward, as this prevents the obscuration by the liver. A further suggestion has been made by Fenwick[2] that in exploring the kidney, the viscus should, as is often possible, be brought well into or out of the wound. It may then be examined by the aid of the Röntgen rays with more chance of success than when it is *in situ*, and that thereby, as he has shown, calculi small enough to escape detection by puncture or palpation may be recognized and treated.

Occasionally it may occur, as in Case XIII., that the absence of pus or other urinary signs will obscure the diagnosis, especially if there be no decided enlargement of the kidney. In Case XVIII. there existed, it is true, a tumor, but nothing pointing toward the presence of a calculus. It was not only of interest as showing the effect of an untreated calculus when no complications occur, but also from the unusual surgical concomitant which happened during the operation of nephrectomy. The patient was the sister of a skilled physician, who had watched and treated her for many years, making numerous examinations of the urine and finding nothing abnormal except the occasional presence of albumin. During the year preceding the operation a diagnosis of tumor of the kidney was made. Cystocopic examination, though difficult, showed some purulent urine, but it was only at the operation that the real state of affairs became known.

The principal accident which complicated the operation was the tearing of the vena cava. The resulting hemorrhage was successfully controlled by immediate suture of the vein, and the accident did not interefere with rapid recovery. No better evidence could be given of the advantage of the large incision used than the ease with which this vein was sutured. Fortunately no edema or other symptom of thrombosis followed, and the vessel without doubt remained pervious. A similar experience has been recorded by Enderlen.[3] During extirpation of the kidney the vena cava was torn by him and immediately sutured. Death occurred forty-five hours later. The cause of death is not stated, but it was preceded by coma

and almost complete suppression of urine. There was some suppuration about the suture, but the closure was perfect, and from within, the lumen was seen to be scarcely narrowed. A thrombus the size of a pea was situated upon the inner side of the suture. Thornton[1] also encountered this mishap during a nephrotomy for renal calculus and pyonephrosis. A curved clamp was temporarily applied to the renal vessels. On its removal after extirpation of the kidney and ligature of the vessels in the pedicle, alarming hemorrhage occurred. The tip of the clamp had opened the vena cava. Death ensued before the bleeding-point was secured. I have also knowledge of yet another accident of this kind which occurred in this city in a similar manner during a nephrectomy and likewise terminated fatally.

CASE XII. *Renal Calculus—Suppurative Pyelitis—Nephrotomy — Subsequent Nephrectomy — Recovery.*—James W., aged thirty-seven years, suffered four weeks before entrance to the hospital with pain in the right loin and frequent micturition, followed two weeks later by chills and fever, and a swelling in the region of the kidney. A needle inserted in the distinct tumor disclosed the presence of thick greenish pus. The urine, which was alkalin, and of a specific gravity of 1030, contained a trace of albumin and a few pus-cells. January 8, 1897, a three-inch incision was made downward and forward from the twelfth right rib, and the kidney exposed and incised. Over a pint of foul, greenish pus escaped. The reticulated cavity was washed out as thoroughly as possible, and drained. Exploration did not detect the presence of a calculus. Under irrigation and drainage, the wound was reduced to a sinus, which showed no signs of closing. The patient left the hospital April 28th at his own request, but returned within two weeks for further treatment. At the site of the previous operation the sinus admitted a probe to a depth of five inches, and at the bottom, on probing, a distinct click was obtained. May 17th the patient was again etherized, and the sinus opened. A stone composed of calcium oxalate, one-half inch in diameter, and weighing 6 grams (90 grains) was extracted with the aid of a vesical scoop. Rubber and iodoform gauze drains were used. There was considerable hemorrhage during the next two days. The tube was removed at the end of six weeks, and the sinus closed soon afterward. This was not a permanent closure, however, and on its recurrence and persistence, about six months later, nephrectomy was performed by one of the other surgeons of the hospital, but no other calculus was found in the removed organ. Seven years later the patient was in good health.

CASE XIII. *Renal Calculi—Nephrolithotomy—Recovery.*—Thos. M., aged fifty-six years, entered New York Hospital, January 12, 1892. For ten years previously he had attacks of renal colic on the right side with passage of gravel and sharp-pointed calculi. These attacks increased in frequency, and during two years there was almost constant lumbar pain. The patient appeared to be healthy, but of a "gouty diathesis," Several examinations did not reveal anything abnormal in the urine. It was alkalin, and presented a specific gravity of 1010.

January 6, 1892, a vertical incision was made from the last rib to the ilium, along the border of the quadratus lumborum muscle, and from its middle a horizontal incision, running forward a distance of three inches, was made. The kidney was freed and explored with a hat-pin. A stone was promptly detected. A longitudinal incision was, therefore, made through the cortex of the kidney posteriorly into the pelvis, and one large stone and about forty small ones were removed. The wound in the kidney was closed by a single catgut suture and the external wound partially sutured and drained with gauze. Blood disappeared from the urine within ten days, and the wound in the loin was superficial within three weeks, at which time the patient left the hospital. The large calculus removed measured 1-inch by ¾-inch, and weighed 7½ grams (112 grains), and the small ones varied in size from that of bird-shot to a buckshot. Their total weight was 9 grams (135 grains). They were composed of calcium oxalate and phosphate. Now, six years later, the patient is in excellent health, having had no urinary symptoms since leaving the hospital.

CASE XIV. *Renal Calculus—Nephrolithotomy—Recovery.*—William S., aged twenty-three years, presented a history of renal colic of some months' duration, with constant lumbar pain, and slight fever. The right lumbar region was tender, but no tumor could be detected. The urine was acid and contained albumin, red blood-cells, and casts. May 3, 1893, the right kidney was exposed by König's curved incision; it was enlarged and lobulated, and a hard mass could be felt in its pelvis. The cortex was incised and a triangular calculus removed. It measured 1.8 cm. (½-inch), 1.8 cm. (½-inch), .8 cm. (¼-inch), and weighed 4.3 grams (65 grains). The wound in the kidney was sutured with catgut, and a strip of gauze placed in front and behind the organ, and the wound elsewhere sutured; it healed readily, and relief of all symptoms followed. The patient has since passed from observation.

CASE XV. *Renal Calculus—Pyonephrosis—Double Nephrotomy — Death.* — Harriet S., aged thirty-eight years, suffered four years from attacks of pain on the left side, usually followed by a chill and fever, and the painful voiding of dark scanty urine, though the general health was fairly well maintained. At the time of entrance to the hospital, to which place she had been sent for operation by Dr. Skinner of Greenpoint, L. I., March 14, 1894, a large smooth tumor occupied the left lumbar region, extending nearly to the iliac crest, and it was not affected by respiration. The urine was alkalin, of a specific gravity of 1012, and nearly half pus. March 21st, the left kidney was exposed by the usual curved lumbar incision, and explored by means of punctures. The presence of a stone was at once detected. The kidney was incised along its convex border, letting out a large quantity of thick foul pus. A large friable phosphatic calculus was then extracted and the kidney flushed with hot water and filled with gauze. The wound was partially sutured. The operation was followed by a temperature of from 101° to 102° F., but it was noted that the urine did not contain any blood.

Two weeks after the operation the patient had a chill which was followed by a temperature of 104° F., and pain in the *right* lumbar region. These symptoms were repeated several times during the following weeks, and the right kidney became so large as to be easily palpable, while the condition of the patient became more and more septic. No increasing tenderness was experienced in the left renal area. Operation was determined upon as giving a slight chance of relief, and the right kidney was exposed May 16th. The presence of pus or stone could not be detected by a needle, though the kidney was very large and soft. An incision was followed by profuse hemorrhage, though no pus was found. The action of the heart failed rapidly, and the patient died within fifteen hours. Though an autopsy was not permitted, yet the inference was plain, after the exploration of the right kidney, that the sepsis was due to another abscess or ab-

[1] *Med. Chir. Transactions*, vol. 72, p. 29.

scesses in the first kidney operated upon. The surgical error made was in not exploring at the last operation the left kidney thoroughly before invading the right one, even though the symptoms pointed so decidedly to the latter organ.

CASE XVI. *Pyonephrosis from Renal Calculus—Nephrolithotomy—Recovery.*—Mrs. E., aged thirty-six years, suffered during ten years with attacks of renal pain, chiefly upon the left side. She was admitted to New York Hospital, October 10, 1894. Eighteen months previously she had passed a number of stones, and more recently the urine constantly contained pus. Her general health was good. By physical examination the right kidney was found to be enlarged and tender. The left kidney was not enlarged, but pressure upon its ureter at the brim of the pelvis was painful. By cystoscopic examination, it was further observed that both ureteral openings were congested, and that the water flowing from the right ureter was purulent, while that from the left appeared to be clear.

By means of König's incision the right kidney was exposed. It was much enlarged, and an aspirating-needle thrust into it disclosed the presence of pus. A two-inch incision was made into its pelvis through the cortex, and two ounces of pus and a large, soft, phosphatic calculus and several small fragments were removed. After irrigation the kidney was filled with iodoform gauze. The transverse part of the lumbar wound was sutured. Operation was followed by a moderate fever. The gauze was removed on the seventh day. Though suppurating freely, the wound granulated well with a constant flow of urine through it. The urine from the bladder also contained a little pus. Within four weeks the patient left the hospital with a small lumbar sinus. Cystoscopic examination showed that purulent urine flowed from the right ureter, and a slightly turbid urine from the left. The water from the bladder was acid, and contained a sediment of pus equal to twelve per cent. of the volume of the specimen.

The calculus with its fragments weighed 35 grams; $1^1/_8$ ounces when dry.

In response to an inquiry concerning her health, the patient wrote, March 10, 1897, as follows: "My general health is very good; good appetite; good color; I am able to exercise freely, and weigh 165 pounds. The fistulous opening in my back still discharges, so that I am obliged to wear constantly a small gauze pad over it, and my urine still contains pus, but never any blood. I have no acute pain in the region of the right kidney, but there is a sensation of weight and fulness there which extends to near the groin on that side, and which is more troublesome on some days than on others. Two or three times within the last six months I have had sharp pain on the left side, lasting from one to five minutes. I feel that I have been very much benefited by the operation."

It may be fairly inferred from the above that there is, perhaps, another calculus in the affected kidney.

CASE XVII. *Multiple Calculi — Pyelonephritis — Nephrectomy — Recovery.* — Mrs. K., aged forty-nine years, was attacked at the age of thirty-seven years with a sudden pain in the left lumbar region. Hematuria followed, and this and the pain continued ten or twelve days. There have since been occasional attacks of pain without fever. Five years ago the urine was found to contain pus. Her physician, Dr. Whittemore of New Haven, who placed her under my care, reported that during the summer of 1895 there was blood in the urine from time to time, but he never found any calculi. When I first saw the patient, during September of that year, there was found, on bimanual examination of the left loin, an enlarged kidney reaching half way to the iliac crest. It was tender on pressure, and yielded when compressed, a grating, rubbing sensation. This was the first time I had been able to elicit this symptom in a case of this kind, for it meant, of course, the presence of more than one stone. The patient had occasional elevations of temperature, but was in good condition.

October 4, 1895, the kidney was exposed by the usual König incision, its distended pelvis opened, and over a dozen calculi extracted, each nearly one-half an inch in diameter, rough and irregular, facetted, and composed of uric acid, covered by phosphates. The finger in the thin renal mass detected many other embedded stones, which in turn were released by breaking down tissue or by incision until the kidney had been split throughout nearly its whole extent. Each separate calculus now extracted was either deep in between a calyx or in the true tissue of the kidney, and was surrounded by a suppurating zone. Under such circumstances, it became impracticable to surely remove all the calculi, and therefore the kidney was extirpated; and its examination afterward confirmed the

FIG. 2.

Showing renal calculus *in situ;* atrophy of the kidney; much thickened perirenal fat, which has been split; patency of ureter shown by catheters passed through it to the calculus.

fitness of the proceeding, as, in all, twenty-seven stones were found, many so small as to permit them to escape detection by the eye or finger. The patient made an uninterrupted recovery, and when seen two years later was in excellent health.

CASE XVIII. *Renal Calculus—Complete Atrophy of Kidney—Nephrectomy—Wound of Vena Cava—Suture—Recovery.*—Mrs. T., aged fifty-two years, enjoyed excellent health until she was forty years of age, when, from no apparent cause, she become very anemic, and lost flesh. The urine was then found to contain a large amount of albumin, but no casts. Under tonic treatment and the free ingestion of milk the health improved and the albumin disappeared from the urine. Subsequent examinations, made from time to time, usually showed traces of albumin, though at times the amount was large. At no time did the urine contain pus.

During the past year the patient had had sharp attacks of pain in the right lumbar region and along the course of the right ureter, followed by tenderness and fulness in

this region and a vesical irritation lasting some days. During November, 1896, an unusually severe attack occurred, and the pain continued several hours. The urine was then turbid with pus, and contained a large amount of albumin. Within ten days it was again perfectly normal. Palpation at this time first revealed the presence of a hard tumor in the right lumbar region, projecting nearly to the level of the umbilicus. Through the aid of cystoscopic examinations, conducted by Dr. Meyer, it was determined with difficulty and after a number of trials that the left ureteral orifice was normal, and excreted clear urine, while the right was surrounded by granulations, and at the time of examination excreted no urine at all.

March 10, 1897, the right kidney was exposed by the usual König incision. The fat capsule of the kidney was readily exposed, but it was adherent on all sides, especially toward the peritoneum, and not to be separated from the kidney beneath. The incision in the abdominal wall was prolonged to the anterior superior spine of the ilium to permit the dissection of the mass which occupied the site of the kidney, and in so doing a rent about an inch long was made in the vena cava. The flow of blood was readily checked by a finger placed above and below the rent, which was stretched out and held taut and immediately sutured with fine catgut, one continuous suture being sufficient to stop the bleeding without invasion of the edges of the rent. An opening into the peritoneal cavity was closed in like manner. The kidney, with its fat capsule thickened and changed by chronic inflammation, was then removed, and the ureter tied with catgut and cauterized, the renal vessels being ligated separately with catgut. When the specimen was cut open, no trace of the kidney other than its ureter and pelvis could be found. The pelvis contained a Y-shaped phosphatic calculus about 1½x1 inches in size. (Fig. 2.) The rest of the mass, the size of a fist, was composed of fatty and fibrous tissue of inflammatory origin. The patient made a perfect recovery, and has since remained in good health.

(To be continued.)

MEDICAL PROGRESS.

Differential Diagnosis of Inflammations and Tumors of the Ileocecal Region —SONNENBURG read a paper upon the above subject which is reported in the *Berliner Klinische Wochenschrift*, September 15, 1897. According to this writer not only inflammations and diseases of the pelvic organs of women may simulate appendicitis, but also affections of the gall-bladder, liver, kidneys, and, under certain circumstances, even the pancreas may confuse the surgeon. It should first be noticed that a perityphlitic exudate is usually immovable; therefore, if a swelling is movable, it is probably not such an exudate. The reverse of this statement is not true, for a carcinoma, for instance, may be immovable. In such cases injection of the intestine with air will assist in clearing up the diagnosis, for if there is present a new growth of the intestine the wall of the latter will be so stiffened that the injected air cannot cause dilation.

Tuberculosis of the ileocecal region may cause infiltration, and thus may resemble either an old perityphlitic focus or a carcinoma, but here the history of the case, which often includes the symptoms of stenosis and completely fails to reveal characteristic attacks of recurrent appendicitis, will usually suffice to establish the diagnosis. Naturally, if the appendix itself is the seat of tuberculosis the characteristic attacks may be present and the differential diagnosis, at least in the early stages, be well nigh impossible.

Of the rarer conditions which may lead to error may be mentioned sarcomata, myomata, dermoid cyst, etc. Various forms of intestinal obstruction, especially invagination, may also give rise to difficulties. In the latter case, the tenesmus and the presence in the stools of bloody mucus, ought to suggest to the observer the correct diagnosis. If there is complete obstruction of the bowels without passage of fecal matter or even of gas, the case is probably not one of appendicitis, as in this trouble intestinal obstruction comes on more gradually.

Abscesses, either from the psoas muscle or from the vertebral column, lie behind the iliac fascia, and are, therefore, flat and not projecting. Moreover, the pain, in acute cases, extends more toward the right extremity and the genital organs; the right thigh is flexed and rotated inward, and peritonitic symptoms are wanting.

The differential diagnosis between appendicitis and diseases of the gall-bladder and liver is peculiarly difficult in those cases in which the perityphlitic exudate is situated high up. Here there are present chills, fever, tenderness, and resistance in both cases. A carefully taken history will still determine the diagnosis in many instances. In colic originating in the gall-bladder or liver the pain usually shoots toward the shoulder, while in appendicitis it extends toward the navel, the most painful point being in the ileocecal region. The most painful point in hepatic affections is close to the border of the ribs. In appendicitis vomiting is not so persistent as in diseases of the liver. In inflammatory or calculous disease of the gall-bladder the high position of the exudate, the relatively slight disturbance of the general system, and the extension of dulness in immediate relation with the normal liver dulness are characteristic points. In perityphlitis a tympanitic zone exits between the abscess and the liver. In both cases there may be jaundice. It must be confessed that empyema of the gall-bladder is often difficult to differentiate from appendicitis. Dilation of the gall-bladder due to obstruction by gall-stones may simulate a chronic form of appendicitis.

The relations of appendicitis to diseases of the female pelvic organs are most important. It has often been remarked that men suffer from appendicitis more frequently than women. The relative frequency is expressed by the figures 60 and 40. It is interesting in this connection to note that the appendix in women has an especial blood-supply which is not found in men, and which is contained in a ligament extending from the right ovary to the appendix. The pelvic diseases which may be confounded with appendicitis are pelvic peritonitis, acute perimetritis, perisalpingitis, and peri-oophoritis. The gynecologists know how often a careless examination may result in a wrong diagnosis, one of the above affections being mistaken for appendicitis, or the reverse. The relation of the suspected tumor to the uterus may usually be made out toward the median line, and, furthermore, the lack of disturbance of intestinal action will point toward a pelvic

trouble. Here again the position of the exudate is of the utmost importance; in appendicitis it is higher up and can seldom be reached from the vaginal vault. In those cases in which the appendix extends into the pelvis and becomes attached to some of the pelvic organs, the position of the tumor is of little assistance in determining the diagnosis.

A pelvic peritonitic exudate usually forms in Douglas' pouch, pressing the uterus against the anterior abdominal wall. Such an exudate is fluctuating in its early stages. On account of congestion the mucous membrane of the rectum is swollen and secretes an abnormal quantity of mucus, and bits of membrane are exfoliated. To these pathologic features may be added several that are clinical. Acute diseases of the adnexa usually begin with vomiting and hiccough, but the seat of the trouble is located from the very beginning in the vicinity of Poupart's ligament. If there is also trouble on the left side, the diagnosis is, of course, clear. In pelvic troubles the pains extend toward the genitals rather than toward the epigastrium; the general condition is less affected; the signs of diffuse peritonitis are wanting. It doubtful cases it may be laid down as a rule that a higher position of the tumor and a localization of the pain on the right side point to an affection of the appendix. In chronic pelvic disease there may be acute recurrences just as in chronic appendicitis, but in the former the symptoms are almost always markedly increased at the menstrual periods, and in chronic cases, moreover, repeated examination will almost always establish a correct diagnosis.

The writer mentioned the fact that he had operated three times in cases of appendicitis which were sent to him with a diagnosis of parametritis. Twice a supposed appendicitis turned out to be an abscess extending upward from the genital organs; in six cases there was combined inflammation of the appendix, and adnexa, and in four cases inflammation of the adnexa followed an operation for appendicitis. He had seen one case in which tubal pregnancy was complicated by appendicitis.

The Mortality of Tetanus with and without Antitoxin.— OWENS and PORTER (*Jour. Amer. Med. Assoc.*, November 13, 1897) report three cases of tetanus, one treated symptomatically, and two with tetanus antitoxin. All proved fatal. A study of the published cases shows two facts, *viz.*, that mortality rates have been but little influenced by the treatment with antitoxin, and that the relation of the period of incubation to the mortality is practically the same whether the antitoxic serum is or is not employed. The writers have analyzed 26 cases in which the serum had been used, and found 12 recoveries, and 14 deaths, giving a mortality of 53.8 per cent. Of those patients who recovered, the shortest period of incubation was six days; of those who died the longest period was twelve days. They are, therefore, of the opinion that those cases in which symptoms appear before the sixth day will die in spite of any antitoxin treatment, and that those in which the development of symptoms is delayed beyond the second week will invariably recover. The Medical Bureau of the Columbian Exposition treated 202 cases in which nail-punctures had been received during the erection of the buildings, in most cases the puncture being made by a rusty nail. Their treatment was as follows: (1) Thorough cleansing of the part with a solution of bichlorid of mercury, 1–1000. (2) Trimming the edges of the wound. (3) Swabbing out the wound with a probe lightly covered with cotton, and dipped in a ninety-five-per-cent. solution of carbolic acid. (4) Drainage. (5) Antiseptic dressing. (6) Rest. Tetanus did not develop in a single case. This shows the value of the preventive treatment which ought to be followed rather than to place dependence upon any possible good effect of serum administered after tetanus has developed.

THERAPEUTIC NOTES.

Treatment of Anemia.—A writer in *Archives of Pediatrics*, October, 1897, recommends the following method as one of the most efficient for the treatment of anemia or chlorosis:

℞ Ferratin . . . . . gram. xv
Natr. bicarb. . . . . gram. ix
Sacchar. alb. . . . . gram. xv.

M. et. div. in chart. No. XXX. Sig. One powder three times daily in a glass of sweetened water.

This is designed for children over fifteen years of age. The dose for children between five and fifteen years is one-half this amount, and one-fourth the amount for children five years of age. An overdose will not do any harm, as about twenty per cent. of ferratin is absorbed without deranging the stomach or causing constipation.

Anemia Treated by Ferratin. — ROLER (*Chic. Med. Rec.*, November, 1897) gives an abstract of three cases, in which treatment by means of ferratin alone, in 3-grain doses, three or four times a day, was efficiently employed. A girl of twelve years, suffering from simple anemia of a marked degree, was practically cured within a month. The number of red blood-corpuscles increased during the administration of ferratin from 2,000,000 to 3,800,000 per c.cm. The appetite improved, constipation disappeared, the cheeks and mucous surfaces were tinged with a healthy red color, and the sensation of fatigue disappeared. Another girl, aged eighteen, suffered three years from anemia and constipation. Ferratin was given, as in the first case, but no marked improvement was manifest until the end of the third week. At the end of the seventh week all symptoms had disappeared. A young man, aged seventeen, suffering with insomnia, anorexia, headache, and fatigue, which latter prevented his engaging in sports, was given 2 grains of ferratin four times daily. Within a month the symptoms had greatly improved, and the blood count showed that the red corpuscles had increased from 2,800,000 to 3,400,000 per c.cm.

For Syphilitic Impetigo.—

℞ Hydrarg. oxid. rubr. } aa . . gr. xxiv
Zinci oxid. }
Resorcini . . . . . gr. x
Vaselini . . . . . ℥i.

A PLEA FOR CHLOROFORM ANESTHESIA.

THE recent introduction to the profession of this country of the Schleich mixtures for anesthetic purposes by Maduro in the MEDICAL NEWS of November 27, 1897, and later by Willy Meyer has led to quite general experimentation with it in the hospitals of New York. Its general use, however, does not confirm that confidence in its absolute safety which the report of Schleich's experience inspired. Its extreme volatility or some other as yet undefined quality seems to unexpectedly overwhelm the patient with a depressing influence, producing great pallor and enfeeblement of the pulse. In one or two instances it has seemed prudent to stop its use and substitute ether.

In view of this experience it would seem to be only a wise prudence on the part of those experimenting with this new agent to constantly bear in mind that its use is still in the realm of experimentation and to watch its effects carefully at every stage. The death-rate from chloroform anesthesia is about 1 in 500, and from ether about 1 in 5000. It will, therefore, require a very extensive experience to establish the merits of the Schleich mixture as compared with chloroform or ether.

In an article in *The Practitioner* for December, 1897, Pringle disputes the assertion which was recently made, "that even in Edinburgh, the birthplace and home of chloroform, medical men and teachers are becoming afraid of its use." The reverse, he says, is nearer the truth.

It may be instructive to consider the conditions of its administration in that city. In the first place there are no especial anesthetists, the anesthetic being given by the various house-surgeons or junior house-surgeons, or by a student. It is usually the rule that two persons must superintend its administration. Chloroform is given by the open or Symes' method, and students are taught to watch the breathing and not to "give chloroform with the finger on the pulse." An ordinary, smooth, hospital towel is folded into a cone, leaving a space at the apex large enough to admit two fingers. The anesthetist holds the lower jaw forward with the fingers of the left hand, keeping the thumb over the mouth to feel the breathing. The chloroform is dropped on the upper part of the inside of the cone and the patient thus receives a sufficient quantity of air mingled with the chloroform.

Pringle kept a careful record of 500 anesthesias. Aside from alcoholic cases, 22 of these patients took chloroform badly, but only 2 of them gave cause for alarm, and this was only momentary. And in both instances, drawing out the tongue and clearing the throat were sufficient to restore respiration.

By reference to reports of twenty-one deaths from chloroform occurring during the past few years, it appears that the operation was usually of a trivial character, such as extraction of teeth, tonsillotomy, circumcision, etc. In sixteen cases a mask, inhaler, or lint was used. Pringle looks upon an inhaler as dangerous. "All apparatus for giving chloroform," he says, "are an abomination." Besides the danger of asphyxiation when an inhaler is used, the patient is obliged to inhale the germs of previous patient's exhalations, for there is no doubt that the air-bag of a frequently used Clover's inhaler contains a great variety of bacteria. In a patient with weak lungs this is a serious responsibility to assume.

The point in the article, however, to which attention is especially called is that it is the imperative duty of medical schools to see that the administration of chloroform is thoroughly taught. If the schools

continue to teach their students simply how to administer ether, putting aside chloroform except in occasional cases, on the ground that it is dangerous, just so long will there be a high death-rate to report from the use of this anesthetic. For as long as chloroform continues to be the pleasantest and the most convenient anesthetic known, just so long will it continue to be used. It is absolutely necessary, therefore, from the point of view of this writer, that every student should have individual clinical instruction and that he should be compelled, before receiving his diploma, to produce a certificate stating that he has personally administered chloroform in a certain number of cases. When this is done deaths from chloroform will be less frequent; for all observers are agreed that many of the deaths which now occur are due to an overdose of the anesthetic.

NEW YORK STATE AND THE AMERICAN MEDICAL ASSOCIATION.

THE annual banquet of the Harlem Medical Association of New York City was held January 15th at the Harlem Casino. There was an unusual attendance both of members and invited guests; one hundred covers were laid. Among the speakers were Surgeon-General Sternberg, president of the American Medical Association; Dr. J. E. Janvrin, president of the New York County Medical Association, and Dr. A. M. Jacobus, president of the Medical Society of the County of New York. A striking feature of the evening's entertainment was the strong and universal sentiment which prevailed in favor of abolishing all differences in reference to codes of ethics, and of uniting, regardless of previous sentiment, in a strong rally in favor of membership in the American Medical Association. The remarks of the three speakers above mentioned abounded in this sentiment.

Many members of the profession in New York State are members of both the State and County Societies, as well as of the State and County Associations. The time seems ripe for the obliteration of all differences and the acceptance by the national association of all who seek its affiliation. In joining the national organization each member pledges himself to abide by its code. This should be a sufficient requirement, and the condition formerly insisted upon, "that a member of the State or County Society should first join the State or County Association," should no longer be required.

No one who did not participate in the discussions which took place at the time New York State was excluded from the national association can realize the bitterness of feeling which then prevailed and the strong prejudices then formed. These smoldering embers may be kept alive if constantly fanned, but will quickly die if ignored. It is sometimes difficult for two contending parties to settle their differences by a mutual conference without the mediation of a third. The American Medical Association has the opportunity of acting in the capacity of peacemaker in a way which will obliterate all lines of distinction in the profession of New York and unite both parties in one organization which shall be loyal to the national association.

The growth of the American Medical Association during the year 1897 was something phenomenal in its history. With the strong prevailing sentiment in the profession of New York in favor of harmony and consolidation, there would seem to be no reason why the increase in membership in 1898 should not equal or exceed that of 1897. The assurance of a cordial welcome at the hands of the American Medical Association is undoubtedly all that is necessary to ensure this end.

FURTHER EFFORTS TO RESTRAIN THE "FAITH-CURE."

WE recently had occasion to refer with satisfaction to the legal treatment which had been awarded the parties responsible for a death which occurred at Camden, N. J., the immediate result of the neglect involved in the application of the "faith-cure." The father of the child and the "faith-cure professor" were promptly arrested and held in custody. We are now enabled to record the fact that this notorious faith-curist, W. F. Randall of Philadelphia, under whose "treatment" the child died of diphtheria, has been indicted by the Grand Jury, and will immediately be placed on trial for responsibility in causing its death. The father of the child, for his failure to provide proper medical treatment, is to be tried on the charges of neglect and cruelty.

This trial promises to be a most important one in that it will be the means of determining in Camden County, N. J., where faith-cure is said to be rampant, whether this practice will continue to be

winked at by the authorities or brought up with a round turn. The Christian Scientists, immediately interested, announce that they are prepared to bitterly contest their rights, and have engaged expert legal counsel to fight the case in the courts. It is sincerely hoped that the New Jersey judges will follow the example of Judge Pennypacker of Philadelphia, who recently refused to recognize the cult of faith-curism as worthy of incorporation, on the ground that the practice of this ridiculously fatuous belief was contrary to public policy and to the laws of the State. By this trial is furnished an opportunity to administer full punishment to those responsible for this latest homicide, and to crush out with an iron hand the iniquitous trifling with human life which, under the guise of a religious belief, the faith-curists practice.

ECHOES AND NEWS.

Plague in Bombay.—During the week ending January 13th, there were 450 deaths from plague in Bombay.

Medical Men in England.—The English Medical Directory for 1898 shows that there are 6081 practitioners of medicine in London, and 15,400 in England in addition to those in London.

Death of Dr. Braymer.—Dr. O. W. Braymer of Camden, N. J., died on the 9th inst. of blood-poisoning, which he contracted while operating upon a septic case at the Cooper Hospital in that city.

Death in Raccoon Hide.—A taxidermist of Reading, Pa., recently died of malignant diphtheria, contracted, it is said, from a raccoon which he had mounted some days previously and which had apparently died of that disease.

Acetylene in England.—Acetylene can be neither manufactured nor sold in Great Britain now save by express permission of the Home Secretary, the prohibition being made in a recent order in Council.—*Scientific American.*

Professor Koch in Africa.—Professor Koch has been invited by the Indian Government to return to India and study the plague, but has declined, for the reason that Germany has engaged his services to study the rinderpest in German East Africa.

Typhus Fever at Glasgow.—The continued spread of typhus fever at Glasgow, Scotland, is attributed to the unsanitary condition of congested parts of that city and to lack of enterprise in destroying the strongholds of the disease.

New Hospital for Pittsburg.—A new hospital, to be called St. Margaret Hospital, will be dedicated by Bishop Whitehead during May next. The hospital is a bequest from John H. Shoenberger, a steel manufacturer of that city, as a memorial of his wife.

Death of Dr. William H. Robb.—The death is announced of Dr. William H. Robb at Selma, Ala. Dr. Robb was a resident of Amsterdam, N. Y. He was fifty-four years of age, and a prominent member of the New York State Medical Society and the American Medical Association.

Yellow-Fever Serum.—Surgeon-General Wyman, of the Marine Hospital Service, and Dr. A. H. Doty, Health Officer of the Port of New York, recently received some of Sanarelli's yellow-fever serum, which was forwarded to them by him from the experimental laboratory at Montevideo.

A Correction.—The strength of the carbolic-acid solution recommended in the article by Dr. Charles E. Lockwood of New York (MEDICAL NEWS, December 25, 1897), for irrigation of the pleural cavity in empyema, should have been given as 1 to 100 (a one-per-cent. solution) instead of 1 to 1000.

Legislation against Hypnotism.—A bill intended to limit the lawful use of hypnotism to licensed physicians will soon be introduced into the New York Legislature, on the ground that its use by irresponsible persons is dangerous and opposed to the public good. The bill should receive the support of all medical men.

Sloane Maternity Hospital Alumni.—The alumni of the Sloane Maternity Hospital have organized a society, and the following officers have been elected: President, Dr. E. A. Tucker; vice-president, Dr. Samuel M. Brickner: secretary, Dr. Ernest A. Gallant; treasurer, Dr. George L. Brodhead. The association will be scientific and social in character.

Post-mortuary Parturition.—In German literature, says the *Lancet*, is to be found a term for which there appears to be no English equivalent, namely, "sarggeburt," or coffin-birth. That is to say, a pregnant woman dies and the body is placed in a coffin and then, before or after burial, an expulsion of the fetus occurs. A few cases of this kind are on record.

Damages for a Broken Jaw.—A woman recently obtained a verdict of $10,000 in a suit for damages which she brought against a New York dentist for injuries to her jaw caused by his unskilful extraction of a tooth. A certificate asserting the fact that the defendant had been convicted by the Court of Special Sessions for practising dentistry without a license, was submitted as a part of the testimony.

Bananas as a Food in Typhoid.—According to Dr. Ussery of St. Louis, Mo., the banana is an excellent food in typhoid fever. This he explains by stating that the banana, although a solid food containing 95 per cent. of nutritive properties, is almost completely absorbed in the stomach, and does not possess sufficient waste to irritate the intensely inflamed and engorged lining membrane of the small intestine.

New Hospital for Berlin.—A new hospital of 1600 beds is to be constructed in Berlin by the municipal authorities. In addition to medical and surgical departments there will be special wards for diseases of women and for venereal diseases, and also a lying-in ward. The institution of special departments is a new feature in municipal hospitals in Berlin, for heretofore they have been divided into medical and surgical departments only.

The Functions of a Medical Society.—In his presidential address to the Glasgow Southern Medical Society, Dr. James Allan summarized the functions of a medical society as the cultivation of good will and the advancement of science. He closed with the sensible statement that "the public will respect and have faith in the profession in proportion as it sees the members of the profession respecting and reposing faith in each other."

Delegates to the New York State Medical Society Instructed.—The Medical Society of the County of New York has instructed its delegates to the State Society to attend the next meeting of that society; to present its dispensary bill to that society for indorsement; to cast their votes in favor of such indorsement, and to vote only for those candidates for offices of the society who individually pledge themselves to indorse the passage of this bill by the Legislature, and to vote against any and all candidates for office who may be opposed to said bill or to any similar bill or legislation.

The Practice of Medicine in Arizona.—The tabulated statement which recently appeared in the MEDICAL NEWS giving the requirements for the practice of medicine in the various States was based upon conditions which obtained in February, 1897. Since that date, *viz.*, on March 18, 1897, Arizona has passed a law stipulating that all applicants for a license to practise medicine in that Territory must not only possess a degree from a reputable medical school, but must also pass an examination before the Territorial Board of Medical Examiners.

Complementary to Dr. Biggs' Address on Sanitation.—The following may be taken as complementary yet antithetic to the opening paragraph of Dr. Hermann M. Biggs' admirable paper, published in the MEDICAL NEWS for January 8th: "Once upon a time when General Sherman was ailing and under the care of a medical friend of ours for quite a long time, he said, 'Doctor, I do not seem to be getting any better for all your medicines.' 'Well, General,' was the reply, 'perhaps you had better take Macbeth's advice and throw physic to the dogs.' 'I would like to do so, Doctor, but there are a number of valuable dogs in this neighborhood.' "

Kings County Effluvium Producers.—Governor Black, following in the footsteps of his two predecessors, Hill and Morton, has issued a precept condemning the offal and garbage works upon Barren Island. The report of the State Board of Health was made October 25, 1897, while the Governor's action bears date of January 7th. We notice that the garbage reduction-plant is in the same group of offensive businesses, or trades, as the notorious fish factory, and the five various condemned plants are alike called upon to apply to the State Board of Health for a permit to conduct their operations in a manner conformable to the regulations of that Board.

Charity and the Queen's Jubilee.—*The Charity Record and Hospital Times* (England) has published its usual annual review of the chief charitable bequests and donations made during the year, and comments upon the fact that the year 1897 has not proved so prosperous for London charities as was hoped and expected. It attributes this in a great measure to the multitudinous appeals made for all sorts of objects in celebration of the Diamond Jubilee. Another object which probably diverted considerable sums from hospitals and other established charities was the Mansion House Fund for the Relief of the Indian Famine, which led to the raising of nearly a million and a half.—*British Medical Journal.*

Health Board Appointments.—At a meeting of the Board of Health of New York City held January 11th, the following appointments were made: Dr. O. L. Lusk of Rockaway Beach, Assistant Sanitary Superintendent for the Borough of Queens; Dr. E. P. Roberts, colored, who has yet to pass the civil service examination, vaccinator for the Borough of Manhattan; Dr. H. D. Goetchius, medical inspector for the Borough of Manhattan. The Board dispensed with the services of Dr. R. M. Wyckoff, deputy commissioner of health of the Borough of Brooklyn. It was also decided to do away with the Brooklyn Department of Bacteriology. Dr. R. B. Randolph of this department was transferred to that of the Borough of Manhattan. E. H. Wilson and J. B. Thomas were removed.

Bill to Enlarge the Board of Health.—A bill has been introduced into the Legislature at Albany enlarging the Board of Health of New York City to four commissioners instead of three, and shortening the term of service from six years to four. A clause in this bill declares that the birth of every child must be reported in writing to the board within ten days of its occurrence by the physician, midwife, nurse, or next of kin assisting at the birth. A fine of $100 dollars is imposed for neglect to comply with this law. The latter clause seems most objectionable. The division of responsibility is a weak point in the bill, and the penalty of $100 is certainly unfair. No physician should be obliged to perform this duty without compensation. The law in England grants a fee of $1 for every such report.

Alcohol and the Russian Death-rate.—An official inquiry into the comparatively larger increase among the Tartar population of the city and government of Kazan has, according to the *British Medical Journal*, brought out some remarkable facts as to the effect of alcoholic indulgence on the death-rate. The Kazan Tartars, numbering about 640,000 souls, have a rate of mortality of only 21 in the 1000, while the mortality among the Russians is 40 per 1000. The general conditions among Orthodox Russians and Mohammedan Tartars are practically the same, except in so far as personal habits are concerned. The medical investigation leaves no room for doubt that the

lesser mortality of the Mohammedan Tartars is directly due to their abstinence from spirituous liquors, in which the Russians indulge freely.

Sailors' Snug Harbor.—The investigation recently made into the affairs of the Sailors' Snug Harbor, Staten Island, N. Y., resulted in the resignation of the governor, Captain Trask. Dr. H. D. Joy, the surgeon of the institution, was temporarily placed in charge pending the appointment of a new governor. The Board of Trustees have finally elected Lieut.-Commander Daniel Delahanty, U. S. N., to be governor. The tenure of office is at the pleasure of the Board of Trustees, and the salary is $5000 a year. Lieut.-Commander Delahanty, who was chosen from more than seventy-five applicants, is at present detailed as executive officer of the United States Battle-ship Texas, but the Navy Department has granted to him a year's leave of absence. He was formerly Supervisor of the Harbor of New York, and is the inventor of the self-dumping garbage scow used by the city.

Pension Examining Surgeons.—The United States Civil Service Commission announces that on March 5, 1898, an examination will be held at Washington and at other places throughout the United States for the position of Pension Examining Surgeon. As the result of this examination vacancies will be filled at Bridgeport, Conn., Lynn, Mass., Washington, Ind., and Vicksburg, Miss. Applicants must be graduates of reputable medical colleges, and not barred by State or other laws. The subjects of the examination are as follows: thesis, anatomy and physiology, physical diagnosis, general and special pathology, and surgery. The subject of the thesis will be upon some common medical theme, and each competitor will be required to write not less than 250 nor more than 500 words. Persons who are legal residents of the places where the vacancies exist will be given preference in appointment. Persons desiring to enter this examination should at once write to the United States Civil Service Commission at Washington for application-blanks, forms 304 and 375, which should be properly executed and promptly filed with the Commission at Washington. No applications will be accepted after the hour of closing business on Friday, February 25th.

Voluntary Determination of Sex.—Attention has been called anew by Professor Schenk to the possibility of determining at will the sex of human progeny. George Macloskie, Professor of Biology at Princeton University, in discussing this subject says: "Sex selection has already been accomplished in the plant world and in some forms of animal life. It has been found that hemp when grown in rich soil produces the female plant, while in scant soil it produces the male. Working bees will, when fed upon very rich food, become queens, and salamanders, when fed upon the fragments of their brothers and sisters will produce almost twice the percentage of females as when they are fed upon ordinary foods. On the other hand, the starving of caterpillars has been found to result in the production of a large percentage of males. Modern biology has established the fact that there is no fundamental difference between the sexes. The eggs of both sexes will live even if unsupplemented by those of the opposite sex, though this supplementation is necessary for healthy growth. The female egg requires rich food and moves slowly, while the male egg requires light food and moves with great rapidity. This is the only difference between them. If it is possible to apply to man, as it is to plants and the lower animals, this principle of selection, the food that the mother of a male would have to take would be only as much in amount as would satisfy her hunger without giving very much sustenance, while to produce females, very rich and sustaining food would be required. I consider that the power of sex selection is a necessary one, and that it will certainly be made a practical thing sooner or later."

OBITUARY.

DOCTOR JOSEPH O'DWYER,

BY W. P. NORTHRUP, M.D.,
OF NEW YORK;
ATTENDING PHYSICIAN TO THE NEW YORK FOUNDLING HOSPITAL.

DR. JOSEPH O'DWYER, the inventor of intubation, was born at Cleveland, Ohio, October 12, 1841, and died at New York, January 7, 1898.

His boyhood was spent in Canada, near London, in which city he attended school. His first studies in medicine were with his preceptor, Dr. Anderson of London, Canada, about 1863. He came to New York and entered the College of Physicians and Surgeons in 1864, and was graduated in 1866. Immediately after graduation he became an interne in the Charity Hospital of New York City, under the then new arrangement by which this institution had its own interne staff, entirely separate from Bellevue. Among his associates forming the new staff were Drs. Leroy M. Yale, F. A. Castle, and P. A. Callan. The visiting staff comprised among its numbers Drs. J. Lewis Smith, Loomis, Flint, Van Buren, and Sayre.

During his service at the Charity Hospital there appeared in New York an epidemic of cholera, the hospital for which was located on Blackwell's Island. Dr. O'Dwyer was placed in charge of this institution—it is generally supposed he volunteered for this service, and it is accurately known that upon him, in his isolated quarantine, the commissioners most confidently relied. During his service typhus fever also appeared as an epidemic. This disease Dr. O'Dwyer contracted. His case was a rather severe one, but after a long illness he recovered without permanent injury to his constitution. He was fond of saying he knew the very hour of his infection. It occurred during an early morning visit, when he was called before breakfast to see a man in a small cell in the penitentiary who had been taken sick during the night. The room was close, and he spent some time examining the patient. Promptly on the day the incubation period expired Dr. O'Dwyer became ill with the disease.

During 1868–9 he became examining physician for the

hospitals under the commissioners of Charities and Corrections. His duties were the distribution of applicants to the various hospitals, to Bellevue and to Charity. During this service classes in physical diagnosis were permitted, and he often, in later life, referred with pleasure to this work. In this year (1868) Dr. O'Dwyer opened his office, on Second avenue near Fifty-fifth street, with Dr. Schoonover. During 1872 he moved to Lexington avenue near Sixty-fifth street, and began the part of his life which brought him into connection with the New York Foundling Asylum (1873) and to the study of intubation.

It was in 1880 that Dr. O'Dwyer "began to think" on the subject of intubation. Tracheotomy was in such bad repute at the Foundling Hospital, with a record of one hundred per cent. of deaths, that the physicians as well as Sisters of Charity saw no excuse for further torturing the children. The first fruit of his "intubation thinking" was a wire spring, which quickly gave way to a spring bivalve speculum. Then came the changes to a "tube of plain oval form," tubes with collar and constriction to receive the vocal cords, and tubes with retaining swell, a tilting back of the upper portion of the tube, thickening and blunting of the lower end, etc., recently detailed by the inventor in an article, entitled "The Evolution of Intubation."[1]

After five or possibly six years of work, thinking and trying, Dr. O'Dwyer reluctantly consented to operate upon patients in private practice. His fourth case was in a prominent family in the practice of the writer. This occurred during the first week of January, 1886. It will be remembered that he began "thinking" on intubation in 1880. Dr. O'Dwyer has occupied in recent years many positions of honor and responsibility, *viz.*, Consulting Physician to Willard Parker Hospital, Lecturer on Intubation at the Post-Graduate Medical School and Hospital, and later at Bellevue Hospital Medical College; Attending Physician to St. Vincent's Hospital and to the New York Foundling Hospital (during twenty-five years), President of the American Pediatric Society, Member of the Council of the Society for Relief of Widows and Orphans of Medical Men, and a member of the Physician's Mutual Aid Association; Consulting Physician to Seton Hospital, besides many medical societiest and the New York Academy of Medicine.

Dr. O'Dwyer was a devout Roman Catholic, the fond father of four boys, a devoted husband, and during the last ten years of his life a constant mourner of his dead wife. He was lonely, retiring, easily hurt by harsh criticism, a poor sleeper, growing year by year more feeble, and struggling harder and harder to get sleep. He was a martyr to intubation. Thinking on its development by day grew into thinking at night. The anxieties of intubation cases, before the use of "antitoxin," no one can know who has not tried to dismiss such a case from mind and to sleep—till the night-bell rings, and it is at once understood that either the tube must be reinserted or removed from a choking child.

Intubation is O'Dwyer's monument. It is equally true that it killed him.

To the close friends of this good and great man intubation seems but an incident of his life. His general good judgment, his well-thought-out opinions, his candor, and his unbending honesty, the simplicity and purity of his life, these rise up in mind to form the memory of him. If to a close companion for fifteen years an unbridled expression may be allowed because it is true and spontaneous, it is this: O'Dwyer's was the sweetest soul God ever gave a man.

[1] O'Dwyer, *Archives of Pediatrics*, June, 1896.

CORRESPONDENCE.

TAPEWORM IN THE ABDOMINAL CAVITY.

To the Editor of the MEDICAL NEWS.

DEAR SIR: In your issue of December 4th I find a letter from Dr. W. F. Saybolt of Wooster University in which he mentions having found a tapeworm in the peritoneal cavity of a live rabbit, and supposing the possibility of such an occurrence being the cause of intestinal perforation in the human being.

In November, 1892, I published the details of a celiotomy for supposed extra-uterine pregnancy, during which I found a tapeworm in the abdominal cavity that had escaped by means of a large ragged opening in the small intestine. The intestine was resected, 2½ inches being cut away. The patient made a satisfactory recovery, and is alive and well to-day. It is interesting to note that all the symptoms were singularly like those of ruptured extra-uterine pregnancy, and this experience adds further confirmation of the repeatedly made observation that the abdominal cavity never ceases to contribute its full share of surgical surprises. The tapeworm was twenty-eight feet in length, and the manner in which it caused destruction of the intestinal wall is the only noteworthy observation to be made in the case. It must have become entangled or rolled into a ball, and in its efforts to free itself caused pressure and gangrene.

FAY M. DUNLAP, M.D.

BLOOMINGTON, ILL., December 15, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

SECTION ON GENERAL MEDICINE OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA — PHILADELPHIA COUNTY MEDICAL SOCIETY—PATHOLOGICAL SOCIETY OF PHILADELPHIA—DR. KEEN'S ILLNESS—RESIGNATIONS FROM THE MEDICO-CHIRURGICAL COLLEGE FACULTY AND BOARD OF TRUSTEES—ALUMNI OF THE JEFFERSON MEDICAL COLLEGE—A TRAINING-SCHOOL FOR NURSES AT ST. CHRISTOPHER'S HOSPITAL—THE INCREASE IN ENTERIC FEVER.

PHILADELPHIA, January, 15, 1898.

AT the last stated meeting of the Section on General Medicine of the College of Physicians of Philadelphia, held January 10, 1898, Dr. William G. Spiller showed *two cases of hysteric hemiplegia*, and *one of hysteric tremor*. The first case of hysteric hemiplegia occurred in a middle-aged man, the onset of whose disease was

first manifested by weakness and numbness of the left leg occurring intermittently in attacks of short duration. Later well-developed zones of hyperesthesia and many other hysteric signs supervened, together with paralysis of the left leg and numbness of the left side. Under appropriate electrotherapeusis the patient greatly improved. The second case of this kind was a woman, thirty-six years of age, who some months after a fall, which occurred six years ago, began to complain of irregular pains, weakness of the left leg, which four years afterward spread to the left arm, tenderness in the left inguinal region, and unilateral hyperesthesia; there was a hysteric gait, the knee-jerks were normal, and there were neither contractures nor facial involvement. This patient also improved under treatment by electricity. The third case was that of a woman who, after having received a fright, began to have uncontrollable twitchings of the left arm and leg, the twitchings later becoming generalized and choreiform in character; on the left side of the entire body there were anesthesia, general weakness, tenderness in the inguinal and mammary regions, increase of the knee-jerk with diminution of many other reflexes, and contraction of the visual fields with preservation of the corneal reflexes.

Dr. Frederick A. Packard reported *a case of stricture of the esophagus* following typhoid fever. The patient was a man who, late in the course of the fever, found great difficulty in swallowing capsules containing sulphocarbolate of zinc. For two months the dysphagia was provoked by attempts to swallow any food other than liquids, and the patient became enfeebled and much reduced in weight. Following frequent passage of bougies, the stricture, which at first measured 2 mm. ($\frac{1}{16}$-inch) in diameter, was sufficiently dilated to relieve the difficulty in deglutition, and the patient rapidly gained in strength and weight. Dr. D. J. M. Miller reported an instance of *a large syphiloma of the liver*, which completely disappeared under the use of "mixed treatment." It was of interest to note that the tumor increased or decreased in size according to the discontinuance or continuance of the administration of the potassium iodid and mercury.

At the last stated meeting of the Philadelphia County Medical Society, held January 12, 1898, Dr. A. Ferree Witmer read an interesting paper on *the clinical aspect of the occupation neuroses*, in which he considered such conditions as writer's cramp, reader's cramp, and the condition somewhat similar to that which occurs in telegraphers as the result of long-continued overuse of the muscles of the forearm and hand. The speakers thought that writer's cramp was due to a cortical lesion rather than to local trouble, and mentioned as predisposing causes urate poisoning, lack of development of the nervous system, and hereditary influences. As a prophylactic the vertical system of handwriting was recommended, and for curative effects absolute rest of the hand and arm, massage, appropriate finger-exercises, and intramuscular injections of strychnin were advocated. Reader's cramp was described as a peculiar twitching of the eyelids, most often more marked on the right side, due to nerve-tire. Drs. Edward Martin and F. W. Patterson read a paper on the *sterilization of surgical instruments with paraform*, and demonstrated the method in detail with a number of different apparatus. Catheters were sterilized by placing them on trays in a closed tin or wooden box upon the bottom of which the powdered paraform was spread. After having been exposed to the paraform vapor for twenty-four hours it was found that the bougies were absolutely sterile, even if they had been purposely contaminated with septic material before the test. This paper was based upon one hundred experiments with the sterilization of instruments by various approved methods, of which paraform only had proved absolutely reliable. Dr. W. S. Forbes read a communication on the *technic and results of an original operation for the liberation of the ring-finger in musicians* by dividing the extensor communis digitorum muscle.

At the last meeting of the Pathological Society of Philadelphia, held January 13, 1898, a valuable paper on *chorio-epithelioma, or the so-called deciduoma malignum* was read by Dr. H. L. Williams. The condition, he said, is observed in women under thirty years of age, during pregnancy, or after abortion, and is characterized clinically by a sudden, gushing hemorrhage from the uterus, a widely dilated os, and an enlargement of the uterus, with a soft, friable condition of its walls. Metastases frequently occur; in the greater percentage of cases, involving the vagina; next frequently, the lungs. Of twenty operations in cases of chorio-epithelioma, collected by the speaker, three died as the immediate result of the operation, three died within six months after the operation, and the remaining fourteen were free from symptoms at the present time. Dr. Williams then went on to describe the gross pathology and the histology of the condition, and took occasion to point out that an absolute diagnosis may always be made by microscopically examining the fragments removed from the uterus during curettage. Dr. Alfred Stengel described a *rare case of cirrhosis of the liver with jaundice and staphylococcic infection of the blood*, occurring in an alcoholic dying from an acute toxemia; and also showed a specimen of gall-stone with enormous distention of the biliary ducts.

The condition of Dr. W. W. Keen, who for a week past has been seriously ill with septicema due to accidental infection while holding an autopsy on a patient who died of peritonitis, is so much improved that his attending physicians have pronounced him out of danger.

During the last two weeks two members of the faculty and a member of the board of trustees of the Medico-Chirurgical College have resigned, the latest resignation being that of Dr. W. Frank Haehlen, professor of obstetrics. It is rumored that these changes in the faculty and trustees of this institution are to be followed by others in the not distant future. The names of the successors to the chairs of Drs. Sajous and Haehlen have not as yet been made public.

The last scientific meeting of the Philadelphia Chapter of the Alumni Association of the Jefferson Medical College was held January 11, 1898, the speaker of the evening being Dr. J. Chalmers Da Costa, who read a paper on *tuberculosis of the kidney*. At the close of the meeting

the members of the Association were tendered a luncheon by Dr. Addinell Hewson. At the annual business meeting of the general Alumni Association of this institution, January 15, 1898, the following officers were elected: President, Dr. William H. Warder; vice-presidents, Drs. John Strobel, I. P. Strittmatter, George McClellan, and George Morehouse; corresponding secretary, Dr. Thomas G. Ashton; recording secretary, Dr. Wilmer Krusen; treasurer, Dr. E. L. Vansant. After the meeting the members were entertained by Dr. W. J. Hearn.

The managers of St. Christopher's Hospital for Children have decided to establish a training-school for nurses in connection with this institution. Miss Edith Mayou has resigned her position as head-nurse of the Royal Victoria Hospital of Montreal to assume direction of the new school.

The largest number of new cases of enteric fever yet reported for any week since the present prevalence of the disease in this city are reported this week, the total number for the week ending January 15th, being 201, or 36 more than last week, with 17 deaths. There were 96 new cases of diphtheria, with 24 deaths; and 62 new cases of scarlet fever, with 6 deaths. The total number of deaths from all causes for the week was 489, an increase of 15 over the number reported last week, and a decrease of 21 from the record of the corresponding week of 1896.

OUR BERLIN LETTER.

[From our Special Correspondent.]

ORGANIC CARDIAC AND VASCULAR LESIONS FROM THE USE OF TOBACCO—A CASE OF NITROBENZOL POISONING—SOME NEW NAMES FOR OLD AILMENTS—THE NEW EDITOR OF THE "ARCHIVES FOR ANATOMY AND PHYSIOLOGY."

BERLIN, January 14, 1898.

MUCH more importance is attached here, one cannot help but think, to the organic cardiac and vascular lesions due to the use of tobacco than is usual in America. A "tobacco heart," with us, is regarded somewhat in the light of a functional cardiac neurosis whose improvement immediately follows abjuration of the habit. Professors Mendel and Leyden each happen to have introduced the subject at clinics during the past week. Professor Leyden says that tobacco indulged in to excess undoubtedly causes myocarditis with true fatty degeneration of cardiac muscular fibers. He admits that the harmfulness of the tobacco habit used to be much overestimated in Berlin, but thinks that generally the tendency of the profession is not to realize how permanent may be the cardiac injury its use may entail.

In Traube's time here it was considered an act of pupilary piety to refer a great many heart symptoms in smokers to the use of the weed. Traube himself had an organic heart lesion which was often the occasion of a good deal of annoyance to him. He insisted on attributing his cardiac symptoms to the use of tobacco, though he never quite gave up his pipe. His persistence in the self-illusion is all the more surprising as his heart trouble was complicated by a kidney affection which etiologically was intimately connected with it. Professor Frentzel afterward had something of the same opinion of his own case, and both are striking examples of how subjectivity of symptoms is apt to ruin accuracy of diagnosis even in great diagnosticians.

Professor Mendel has noted in a large number of cases of heavy smokers that the arteries become thickened, hardened, and tortuous long before the atrophic changes of old age begin to be manifested. He has especially noted this arteriosclerotic condition in persons between thirty and forty-five years of age, as he believes, from over-indulgence in tobacco. Professor Mendel himself is a smoker, so that there would seem to be no question of any unreasonable fanatic opposition to "the pipe that soothes" in his rather startling bit of clinical experience. Professor Leyden does not smoke, which may somewhat decrease the value of his opinion in the matter. He assured his students the other day, however, that he perfectly remembered the acute toxic effects of tobacco on one who was unused to it, though he considered that this was a chapter in the toxic effects which did not require elaboration before medical students.

Cases of nitrobenzol poisoning are growing more and more frequent as the economy of the use of this artificial coal-tar product, instead of the more expensive genuine oil of bitter almonds, in the manufacture of soaps, perfumes, etc., becomes clearer. A carefully observed case of poisoning by it has just been reported from Professor Furbringer's clinic at the Friedrichshain Hospital (*Deutsche medicinische Wochenschrift*). Curiously enough the case corresponds exactly in the manner of ingestion of the poison with another odd case described sometime ago. Both patients were draymen, who, while hauling the large flasks in which the nitrobenzol is shipped, took an unknown quantity of the liquid in order to find out what it was like.

In the last case death occurred within five days. A febrile temperature of between 39° and 46° C. (102.5° to 104° F.) persisted until the fatal termination. Though the blood was almost tar-like in consistency and black in color, no changes could be found in its cellular elements. There were no differences in size, shape, or color of the red corpuscles, no poikilocytes, or micro- or macrocytes. There was no leucocytic reaction to be observed and no noticeable change in the white cells, except, perhaps, a lessened tendency to ameboid movements.

Spectroscopic examination showed absolutely normal blood. There were at no time during the five days, though they were carefully looked for, the two dark absorption bands of meth-hemoglobin, which have been found in some other cases. On the other hand, the spectral bands of oxyhemoglobin were present. There was a reducing substance in the urine which gave a reaction with all the ordinary sugar tests, bismuth as well as copper. There was no blood in the urine, however, and no albumin. The autopsy produced absolutely negative results, except for the presence of the black, tar-like blood. There is evidently here some important discoveries awaiting some one whose opportunities and investigating spirit will enable him to solve the mystery of the fatality of the poison.

With the problem would seem to be involved certain

questions as to the physiologic functions of blood plasma which are important in their bearings on clinical medicine in a field that is as yet practically unworked. In the case in question intense trophic disturbances were evidently at work, though apparently none of the cellular elements of the blood were involved. Though in principle alcohol would seem to be contraindicated, the poison being an analogue of the alcohols, and therapeutists advise against its use, in this, as in other cases of like nature, alcohol seemed to be the drug which accomplished most in regulating the circulatory mechanism and in relieving the symptoms of intense depression which developed.

Sometimes one is surprised to find how much more important an old friend may seem in a new dress, and the same thing would seem to be true for some familiar ailments and the new terms applied to them. Careful analysis by the specialists of the disturbances of speech has separated various forms of what used to be plain stammering, and furnished new terms derived from the Greek. Inability to properly pronounce the letter "g" is called paragammatismus, the letter "r," pararhotismus, "l," paralambdismus. The difficulty of enunciating "s," which has been known to ordinary mortals for many a day, now becomes the scientific parasigmatismus. It will surely soothe the mother's anxious heart much better to know that her young hopeful is suffering from one of these "ismuses" than that he merely stammers or lisps.

Some defects which used to be considered somewhat more the result of intellectual hebetude or of pigritia indurata (the medical term for chronic laziness) are being arranged in the same category. The unconquerable defect which some people have of not arranging their words according to the usually accepted rules of syntax becomes in this way an intellectual ailment—agrammatismus. The corresponding defect of not always arranging the letters of words according to the usual rules of spelling, becomes an orpara-orthographismus. As this latter is in many cases undoubtedly a psychic ailment which no amount of hard work seems able to entirely eradicate, perhaps the new classification of these things as real mental defects is, after all, a rational one.

Upon the death of Professor Du Bois Reymond the Physiological Society of Berlin assumed the editorship of the Physiologic Department of the *Archives of Anatomy and Physiology* which he had held. Professor His is the editor of the Anatomic Department. With the beginning of 1898 Professor Engelman, who succeeded Du Bois Reymond in the chair of physiology at Berlin, assumes the editorship of the department which his predecessor had so ably managed for so long a time.

Recovery from Chloroform Poisoning by the Use of Large Doses of Strychnin.—REID (*Brit. Med. Jour.*, November 20, 1897) details a case of chloroform poisoning in which ½-grain of strychnin was injected subcutaneously in the course of three hours. By this means, as well as by artificial respiration and the use of an electric current of fifty volts (one pole of the battery being placed over the respiratory center and the other over the ensiform cartilage), the patient was kept breathing until the effect of the chloroform had passed away.

ATROPHY OF THE KIDNEY CAUSED BY OBSTRUCTION OF THE URETER—NEGATIVE ACTION OF SEWER-AIR IN RAISING THE TOXICITY OF DIPHTHERIA BACILLI—CAUSES OF THE VARIATIONS IN THE SIZES AND SHAPE OF THE COLI BACILLUS—OBSTRUCTION OF LABOR BY OVARIAN TUMORS IN THE PELVIS—SOME CASES OF PANCREATIC CYST—DEATH FROM INTESTINAL TOXEMIA—FIFTEEN CONSECUTIVE CASES OF INTUSSUSCEPTION.

AT a meeting of the Pathological Society, December 7th, BRADFORD spoke of *atrophy of the kidney caused by obstruction of the ureter*. With such a result in mind experiments were performed upon dogs. One ureter was ligatured in two places and divided. From ten to forty days later it was brought to the surface and sutured in the skin. When it was opened about two ounces of fluid was evacuated. The fluid was clear in nine cases and purulent in three. The animals were killed at periods varying from seven to fifty days after the second operation. In each case the kidney, the ureter of which had been tied, was found to have resumed its normal shape, but had shrunken to one-fourth its usual size. Microscopically, it could be seen that some tubules had disappeared, but the main cause of the atrophy was the crowding together of the tubules and the small size of their cells. The length of time during which drainage was allowed to go on before the animal was killed did not appear to have much influence on the degree of atrophy.

SHATTOCK read a paper on the *negative action of sewer-air in raising the toxicity of non-virulent diphtheria bacilli*. It has frequently been surmised that the inhalation of sewer-air determines the occurrence of diphtheria, although diphtheria bacilli cannot be conveyed in this medium since they are not disengaged by evaporation from the fluids in which they are grown. It is possible that a non-virulent diphtheria bacillus such as is present in the throats of many individuals may, in consequence of the inhalation of sewer-air, become virulent and give rise to diphtheria in the throat. In order to determine this point the author had grown non-virulent diphtheria bacilli in Duclaux flasks in broth, and over the surface of the medium sewer-air was continuously and slowly drawn by means of a water-pump. The only noticeable effect was a retardation of the growth of the bacilli. Their virulence was not increased, as was proven by subcutaneous injections in guinea-pigs. Shattock regards these results as interesting, although, as he stated, they do not exhaust the question.

HASLAM discussed the *causes of the variations in the size and shape of the coli bacillus*. These variations, according to his experiments, are due to the different media upon which the bacillus is grown. For example, if in a glucose solution the nitrogenous matter is increased, he finds a corresponding increase of the longer forms of the bacillus. Growths on glucose with less proteid matter produce shorter forms, etc.

At a meeting of the Obstetrical Society, December 1st, MCKERRON read a paper on the *obstruction of labor by*

ovarian tumors in the pelvis. One hundred and eighty-three cases had been collected in which ovarian tumors occupied the pelvis during labor. As shown by recent publications there is a wide difference of opinion as to the most satisfactory treatment of this complication. The reader drew the following practical conclusions: Reposition should in all cases be first attempted. When it fails a selection should be made, according to circumstances, from the following operative measures: Puncture, Cæsarian section, abdominal or vaginal oophorectomy.

At a meeting of the Medical Society, December 13th, DORAN described a *pancreatic cyst* occurring in a woman aged twenty-four years, which was *successfully treated by anterior incision and drainage.* The tumor was situated in the lesser peritoneal cavity, the lesser omentum and stomach formed the front of its capsule, and the transverse mesocolon was entirely below it. The fistula discharged for five months and then closed spontaneously. Stress was laid upon the surgical importance of defining peritoneal relations and the exact attachments of the cysts during operation. Such a cyst may lie in the lesser peritoneal cavity, in the fold of the transverse mesocolon, or in the general peritoneal cavity. When it occupies the lesser peritoneal cavity it has probably burst through the peritoneum in front of the pancreas. This would account for the complete freedom of the ascending layer of the transverse mesocolon, which is found entirely below the cyst in many of these cases. When a pedicle is formed, even if it includes the tail of the pancreas itself, total removal of the cyst is justifiable. Removal of a sessile cyst, on the other hand, involves risk of damage to the splenic and other large vessels and to small arteries and veins in the friable pancreatic tissue. The statistics of drainage in the treatment of sessile cysts seem very satisfactory.

ROLLESTON and TURNER contributed the notes of a *case of peripancreatic cyst.* The patient was a man aged thirty years, who complained of epigastric pain of six-months duration. During five months the feces had been clay-colored. Jaundice had existed three months. Examination showed a tense tumor containing thirty ounces of dark-brown fluid; no bile or pancreatic ferments were found therein. Although the cyst evidently arose in the neighborhood of the pancreas it was not immediately connected with it. Still it may have had its origin in a pancreatic hemorrhage. The cyst was tapped, drained, and the patient made a good recovery.

MALCOLM excised a *multilocular cyst of the tail of the pancreas* which simulated hydronephrosis. There was much difficulty in arresting the hemorrhage, but this being finally accomplished, the abdomen was closed without drainage.

At a meeting of the Clinical Society, December 10th, GOULD read a paper on a *case of acute intestinal obstruction relieved by operation, in which death from intestinal toxemia occurred on the ninth day.* The patient was a man aged forty-three years. The operation was performed on the fourth day, and a coil of small intestines twisted upon itself was found adherent in the pelvis. The intestine was liberated and gas and fluid intestinal matter at once passed into the cecum. On the following day the patient passed gas and a small amount of fecal matter by the rectum, and two days later he had a large evacuation of the bowels. In spite of this favorable symptoms, intestinal matter was regurgitated into the stomach, from which organ it was several times removed by means of a tube. Afterward the patient took fluid food well, and there were no signs of peritonitis; but gradually he passed into a condition of stupor, deepening into coma, accompanied by a slightly quickened pulse, quickened, deep, and noisy respiration, a subnormal temperature which was lower in the rectum than in the axilla, profuse diarrhea, the motions being of a peculiar odor, and of a grey-green color. The skin was covered was a dark erythematous rash. These symptoms reached their maximum on the sixth day after the operation. Four pints of a saline fluid were injected into a vein and immediately all the symptoms passed away. He relapsed next day, and saline fluid was again injected with marked benefit. Two days later he again become unconscious and died comatose in spite of a third injection of salt and water. The urine throughout the illness contained a great excess of indican, and another chromogen whose nature was not determined.

COLMAN mentioned a case in which *intestinal toxemia caused mental excitement, and not coma,* as in the preceding case. The patient was a woman forty years of age, who had a large fecal impaction in the ascending colon. Under treatment the mass became softer and she began to pass fecal matter in considerable quantity But on the third day she become delirious. She had no knowledge of her surroundings, and had hallucinations of hearing and vision which took the form of animals running about her bed, which, however, did not terrify but only amused her. There was no history of abuse of alcohol or of the administration of belladonna. Her temperature was low and her pulse even. By means of frequent enemata the bowel was completely emptied and the delirium entirely passed away.

BARKER read a paper on *fifteen consecutive cases of intussusception*, in eight of which injections were tried and failed, and subsequent events showed that in twelve of the fifteen reduction could not possibly have been effected by injection, even had it been employed when the patients were first seen. Unless, therefore, a case is seen a few hours after the onset of the symptoms, it is safer to at once proceed to open the abdomen. The danger of ventral hernia may be reduced by making a very small incision. An incision long enough to admit one finger is often sufficient.

Berlin.

A REMARKABLY PROLONGED CASE OF STAPHYLOCOCCIC INFECTION—RELATION BETWEEN OVER-FATNESS AND DIABETES—AN APPARATUS WHICH CURES MIGRAINE IN THREE MINUTES.

At a meeting of the Medical Society, December 1st, WOHLGEMUTH narrated a *remarkably prolonged case of staphylococcic infection.* The patient, a man aged fifty-six years, was operated upon for hemorrhoids. Catheterization was necessary, and cystitis and epididymitis followed. As he slowly recovered from these troubles suppurative inflammation developed in the left sterno-

clavicular articulation, requiring incision. Six months later an abscess developed in the right gluteal muscle, with spondylitis of the fourth and fifth dorsal vertebræ, for which a plaster jacket was applied. Fourteen months after the original infection there was purulent and bloody expectoration, in which no tubercle bacilli could be demonstrated. For the next three years there were occasional attacks of pain in various portions of the body, and stiffness of the muscles so that at times walking was almost impossible. Five years after the infection, without apparent cause, an abscess developed in the right thigh, from which there was evacuated a greenish pus containing the staphlococcus albus in pure culture. In similar cases which run a more acute course, staphylococcus aureus has been found.

HIRSCHFELD called attention to the *relation between overfatness and diabetes.* It often happens that very fat people will show glucose in their urine after a meal containing a fairly large quantity of sugar. Hirschfeld found that the glucose disappeared from the urine of those fleshly diabetic patients who were being treated for obesity, though not placed upon a strict diabetic diet. Instead of receiving 10 ounces of hydrocarbons per day, they were receiving only 3⅓ ounces, and an abundance of active exercise was prescribed. The speaker expressed the opinion that the glycosuria which so often follows traumatic neuroses is due to an excessive diet combined with a lack of active exercise. There would seem to be some relation between obesity and diabetes.

HANSEMANN said that in *seventy per cent. of diabetic patients he had found some alterations in the pancreas.* Of especial interest in this connection is a lipomatosis of the pancreas which, like that of the capsule of the kidney or of the heart, may exist either in connection with the general excess of fat, or, on the other hand, may be found in lean individuals. In such a condition little is to hoped for from treatment, for it is scarcely to be supposed that if the fat tissue has taken the place of the pancreatic tissue to any great extent, that a regeneration of this organ can occur.

At the session of December 8th, EWER showed an *apparatus which by slight, very rapid, and equal vibrations of the body is able to cure within two or three minutes all nervous pain, especially migraine.* The apparatus is operated by electricity, and consists of a small motor whose core revolves with great rapidity. This core at one end is bent a little from its center, so that with each revolution it strikes a rubber knob, giving to it a little thrust. If this knob is held against the surface of the body the rapid revolution of the motor transmits to it a quick trembling, with the relief of pain above mentioned. The form of the instrument may be altered according to the portion of the body upon which it is to be used.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE.—SECTION ON GYNECOLOGY AND OBSTETRICS.

Stated Meeting, Held November 24, 1897.

DR. SIMON MARX, M. D., in the Chair.

ECTOPIC GESTATION, COMPLICATED BY TYPHOID FEVER.

DR. JOSEPH BRETTAUER showed specimens removed on the same day from two cases of ectopic gestation. The patient in the first case was twenty-nine years of age, the mother of two children. Operation was performed August 17, 1897, partial rupture having occurred. A large amount of fluid blood was removed from the abdominal cavity. The patient did well until the fourth day when the temperature ran up to 105° F., and the pulse to 160. The woman, however, did not present the appearance of a patient suffering from acute septic infection. On the following day the temperature fell to 100° F., and the pulse to 112, the general condition was improved, and the symptoms of the preceding day were ascribed to absorption of the serum which was left in the abdominal cavity. The patient continued to improve until September 2d, when the temperature suddenly rose to 105° F., and violent headache was complained of. The following morning there was a chill which lasted twenty minutes and was followed by a temperature of 106° F. Physical examination failed to reveal anything which would account for the high temperature. There was no exudate, no resistance whatever in the pelvis, the uterus was freely movable, the abdomen perfectly flat, and the wound had healed by first intention. As the spleen was found to be somewhat enlarged, malaria was suspected and a specimen of blood was examined for the plasmodium, with a negative result. A consultant was called in who found the spleen much enlarged and a number of typical rose-colored spots upon the chest and abdomen; there was also a dicrotic pulse. Widal's test was employed, but with a negative result. On September 5th the patient was removed to the city. The temperature at that time was 103° F. in the evening and 101.5° F. in the morning, and this rise and fall continued until the 12th, when it became normal and remained so. In view of the constant negative results of Widal's test the diagnosis of typhoid fever was not clearly established, but the speaker was, nevertheless, inclined to regard the condition as one of typhoid fever, possibly of an abortive type. The fact that the patient was taken sick at a summer-resort, where typhoid fever occurred at the time quite epidemically, was in a small measure responsible for this conclusion.

The second specimen showed a ruptured tubal pregnancy removed from a patient on the same day as that upon which the first was operated upon, and, although gestation had apparently continued over three months in this case, the fetus was only about three-fourths of an inch long, its growth having evidently been arrested by hemorrhage into the wall of the unruptured tube as was clearly shown in the specimen.

VAGINAL ENTEROCELE.

DR. PHILANDER A. HARRIS of Paterson, N. J., presented a case of vaginal enterocele. The patient was a married woman, twenty-four years of age, the mother of three children, and she has complained since the birth of her last child of a constant bearing-down sensation in the vagina, accompanied by a "dragging," which she refers to the umbilical region. These symptoms are especially distressing when she is on her feet, and in doing her work she is obliged to occasionally stop and lie down for a time. About a year ago an operation for repair of the perineum and of the cervex uteri was performed in Chicago. This, however, did not relieve the symptoms, and her condition has since become much worse. Physical examination shows a bulging of the posterior cul-de-sac which appears at the vulva. There is no rectocele or cystocele.

At the request of DR. HARRIS, the Chairman appointed DRS. GARRIGUES, BOLDT, and BRETTAUER a committee to examine the patient.

DR. HENRY J. GARRIGUES reported as follows: We found a protrusion of the posterior vaginal wall which extends down to the vulva and which at first sight resembles an exaggerated rectocele. Upon further examination we found that this protrusion leads into a transverse opening, large enough to admit three fingers, in the pelvic floor behind the cervex. There is no doubt as to the diagnosis of vaginal enterocele.

FIBROSARCOMA OF THE UTERUS.

DR. GEORGE H. BALLERAY of Paterson, N. J., exhibited a specimen of fibrosarcoma of the uterus which he had removed by vaginal hysterectomy from a patient sixty-two years of age. Menstruation had ceased fifteen years ago, and there were no symptoms referable to the uterus until last March, when a discharge of blood from the vagina was noticed which continued up to the time of the operation. The patient was in fairly good condition, but showed the effect of loss of blood. Vaginal examination revealed a small mass to the right of the uterus, the latter being small and still movable. The patient was a nullipara with an extremely narrow vagina, and much difficulty was experienced in performing the operation, it being necessary to divide the perineum and make an incision anteriorly before it was possible to bring down the uterus. A cyst containing bloody serum was found in the posterior part of the mass, and it was ruptured during removal. Clamps were exclusively employed, although the speaker said it was his usual custom to clamp only the lower segment of the broad ligament, retrovert the uterus, and tie the remaining portion of the ligament. The patient is at present in good condition and promises to make a speedy recovery.

DR. HIRAM N. VINEBERG: I would like to ask if a microscopic examination has been made in this case.

DR. BALLERAY: No examination with the microscope has been made as yet. The diagnosis was made entirely from the clinical history which pointed strongly to malignant disease. My experience with the microscope has not been reassuring, and my confidence in this method of making a diagnosis has been rudely shaken—so much so that I would rather trust to the clinical history than to a microscopist's report in a case of this kind. However, the specimen will be submitted to a pathologist.

DR. VINEBERG: I agree with Dr. Balleray that he did perfectly right in this case without a microscopic examination having been made. The diagnosis, however, can be verified by a pathologic examination. If this cannot be relied upon, we will have to go back on our pathology altogether.

KRAUT'S DRY-BED.

DR. FISCHER presented an apparatus, which consists of a wicker bassinet so arranged that a rubber bag within it receives the urine and feces of the child. The same principle has also been applied to invalid beds for cases in which there is incontinence of urine and feces. These beds are in use in many hospitals in Europe.

REPORT OF A CASE OF NEPHRECTOMY FOR STRICTURE OF THE RIGHT URETER AND EARLY TUBERCULOSIS OF THE KIDNEY.

DR. HIRAM H. VINEBERG reported such a case and exhibited the specimen. The patient was a woman, forty-eight years of age, married twelve years, the mother of five children, and she had passed the menopause four years previously. The symptoms began six months ago, and consisted of pain in the back and loins accompanied by nausea and vomiting. Three months later she came under the observation of Dr. Manges who administered methylene blue with apparently good effect at first. At this time a small quantity of pus was found in the urine. The patient also complained of pain in the hypogastric region extending to the right lumbar region. Micturition, which had been frequent from the beginning, now became still more so, and was very annoying. When seen by the speaker the right kidney could not be distinctly palpated and certainly was not enlarged, but a cord-like structure as large as a lead-pencil was made out in the anterior vaginal fornix, running upward and to the right. This apparently was the thickened right ureter. Cystoscopic examination with the patient in the knee-chest position showed the left ureteral orifice seemingly normal except that there was a small bleeding-point near it. The right orifice was swollen and irregular in outline and presented the appearance of a nipple. A number of small, red spots were scattered over the lining membrane of the bladder. Upon introducing a catheter into the left ureter clear urine was withdrawn, but even a small-sized ureteral sound could not be made to enter the right ureter on account of a stricture about one inch from the outlet. A diagnosis of stricture of the right ureter and localized cystitis was made, and the latter was treated by applications of nitrate of silver with the result that the frequent micturition and hypogastric pain were relieved. At this time repeated examination of the urine did not reveal tubercle bacilli, and the patient's condition improved so much that complete recovery was looked for. In August, however, she was seized with a severe attack of pain in the right iliac region which terminated with a discharge of bloody urine. Urinalysis disclosed nothing to indicate the presence of stone, and another cystoscopic examination showed

the right ureteral orifice in the same condition as before and the bladder surface perfectly normal. A tuberculous condition of the kidney was suspected and the patient advised to go to Baltimore to consult Dr. Howard A. Kelly. The latter made a diagnosis of stricture of the right ureter and advised operation and removal of the kidney if the symptoms could not be relieved in any other way. Operation was performed in October at St. Mark's Hospital, the right kidney being removed after it was ascertained that it did not contain a stone. The patient made a good recovery.

The specimen showed a kidney neither long nor narrow; length, 11 cm.; circumference at lower pole. 13 cm.; at upper pole, 10.5 cm. Upon making a longitudinal section two abscesses were disclosed, one, about the size of a small bean, situated immediately beneath the capsule in the cortical layer at the junction of the middle with the upper third; the other, about the size of a split pea, situated just internal to the first, but still in the cortex of the kidney; the wall of the smaller abscess was corrugated like that of a corpus luteum. The pus in these abscesses contained tubercle bacilli in abundance. A short distance above the site of the abscesses, in the cortex directly beneath the capsule, was a group of miliary tubercles. The pelvis of the kidney, as well as the upper part of the ureter, was normal in appearance.

DR. H. J. BOLDT: This case has interested me very much. It is fortunate that the woman developed stricture of the ureter which gave rise to the symptoms which lead to the condition of the kidney being discovered. I recently observed a case of tuberculosis of the kidney, but there was no stricture of the ureter. The diagnosis was made by the enormous dilatation of the ureter which was ascertainable by palpation. The bladder was also affected, and was evidently the primary seat of the disease, as was probably the case in Dr. Vineberg's patient. In my case there was not enough thickening of the bladder end of the ureter to make it apparent on palpation. The prognosis is good when the patient is seen early and a radical operation performed.

DR. THOMAS H. MANLEY: I have taken considerable interest in this subject of tuberculosis of the kidney, and, in view of the fact that in the case under discussion pus-corpuscles were found in the urine, it seems to me that this should have led to a diagnosis of tuberculous kidney and a more conservative operation. If the disease was localized, the abscess could have been curetted and treated like any other abscess, and recovery would have followed.

DR. VINEBERG: In answer to Dr. Boldt I would say that at the first examination some thickening of the ureter was detected, and I was fairly confident that there was some trouble there. In regard to the frequent micturition, this was one of the first symptoms, but at the same time there was a cystitis present. This symptom disappeared when the latter condition was treated.

As to the criticism made by Dr. Manley, I can only say that the stricture of the ureter alone would have necessitated the removal of the kidney. Apart from that the kidney was extensively adherent to the perirenal fat, there were two abscess cavities, and a general tuberculous condition of the whole organ, and I do not think that justice would have been done to the patient if the kidney had not been removed.

DR. MANLEY then read the paper of the evening, entitled

SOME SPECIAL FEATURES IN HERNIA AND HERNIATED CONDITIONS IN THE FEMALE.

The author dealt with the subject in the most exhaustive manner, giving in detail the statistics of numerous authorities as to the relative frequency of the different forms of hernia in the male and female subject at the various periods of life, and he emphasized the necessity of carefully recording the sex and age of the patient and the symptoms when reporting cases in order to make such records of future value. According to his deductions, congenital hernia is more frequently found in male than in female infants, but the female is much more prone to develop hernia, especially the umbilical variety, in later life on account of increasing relaxation of the abdominal muscles incident to child-bearing. Hernia in the male is generally congenital. Strangulation is more apt to occur in femoral hernia, and the operative mortality is greater in this than in any other variety. In speaking of hernia following operation, the author quoted Bland Sutton's statement that abdominal section often leaves a condition far more serious than the one for which it was performed.

DR. GARRIGUES: As to the relation between sex and hernia, inguinal hernia is much more common in the male, and the reason for this is undoubtedly the fact that in man the inguinal canal is so much larger than it is in woman on account of the passage of the spermatic cord through this canal. On the other hand, femoral hernia is much more common in women because of the relaxation of the abdominal wall in all directions due to child-bearing, and also because of the difference in anatomic structure. The female pelvis is much flatter and more horizontal than that of the male, consequently Poupart's ligament is relatively longer and tends to make the femoral canal wider and consequently weaker. This anatomic difference acts as a predisposing factor in the development of femoral hernia. In regard to umbilical hernia, this condition is frequently found in new-born children of both sexes. In later life it is more common in women. Inasmuch as distention of the abdomen by pregnancy is such a fruitful cause of hernia in women, one would expect to find this condition in cases where unusual stretching of the abdominal walls has been caused by multiple pregnancy and hydramnion, and yet such is not the case. Femoral hernia in the male is often due to varicocele. The large swollen vein distends the crural canal, and thus favors the passage of the gut through it.

In regard to the relative value of abdominal and vaginal hysterectomy, it is often claimed by the adherents of the latter method that one of the advantages connected with it is that the danger of abdominal hernia is obviated. I personally know of a case in which vaginal enterocele followed hysterectomy *per vaginam*, and the fact that this does occur after vaginal incision should make those who favor this method exercise great caution. It is a safe

plan to keep the patient in bed for three weeks subsequent to operation in order that the vaginal wound may be completely healed.

As to the ventral hernia, this is fortunately becoming constantly more unfrequent after abdominal operation because care is taken to unite separately the different structures of the abdominal walls, and also because the drainage-tube is used very much less now than formally. In regard to the prevention of hernia, I take it to be very desirable as a prophylactic measure that women should strengthen their abdominal muscles, and for this purpose I would call especial attention to the value of bicycling. In regard to treatment, in my opinion it is better to perform a radical operation than to apply a truss. The operation for radical cure is not dangerous, Dr. De Garmo has reported 250 operations of this nature without a single death.

DR. HERMANN L. COLLYER: In my experience umbilical hernia in women is most often due to pregnancy. I have also seen many cases of inguinal hernia in the female. Recently there came under my observation a case of vaginal hernia occurring after vaginal hysterectomy. In these cases, however, it will generally be found that the intestine is adherent and cannot prolapse very much. To my mind, all hernia should be operated upon, palliative treatment being employed only until such time as the patient makes up his or her mind to submit to operation.

DR. BRETTAUER: The author did not refer to that form of hernia which occurs after Alexander's operation. I have seen eleven cases of this kind. All came under observation at the clinic and in all healing of the wound was by granulation. I have here a photograph of one of the patients which shows such a condition in its extreme form.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held December 7, 1897.

THE President, B. SACHS, M.D., in the Chair.

TOXIC TREMOR AND HYSTERIA IN A MALE.

DR. J. ARTHUR BOOTH presented a man whom he had first seen one week before at the French Hospital. The patient, sixty-one years of age, had been engaged up to 1885 as a mirror polisher, using mercury, and since then in the same occupation, but using silver instead of mercury. His family history is negative as regard nervous disease. At the age of twenty-two years he contracted syphilis, and was treated for this for some time. He then enjoyed good health up to thirteen years ago. At this time he fell on the street with both lower and upper extremities in a state of clonic spasm. He was taken to the Boston City Hospital, and subsequently was under the care of Professor Charcot for several months. He returned to this country during 1887, and resumed his work of mirror polishing, using silver. He has had three or four attacks of tremor. The present illness began November 17th after having worked very hard for some time previously. The tremors presented by the patient, the speaker said, certainly resembles those observed in cases of mercurial poisoning. A very slight tap on the body would set up a pitiable degree of reflex tremor. There is no nystagmus, but there is slight ataxia. It was found that the tremor is greatly increased when attention is drawn to him, and for this reason it seemed not improbable that there is a hysteric element in the case. There are no bladder or rectal symptoms.

DR. W. M. LESZYNSKY said that the disease seems to be a functional one added to the evident toxic tremor. The fact that he had had such attacks and had recovered from them would seem to confirm this view.

NEURITIS FOLLOWING AN INFECTED VACCINATION.

DR. W. B. NOYES presented an infant who had been vaccinated last spring, the wound becoming infected. When the bandages had been removed, it had been found that the child could not move the arm. Examination showed that the deltoid, biceps, and the muscles supplied by the ulnar nerve were involved. They did not react to faradism, but gave the reaction of degeneration. The case seemed to him, at the time, to be a neuritis resulting from an infected wound; but two other opinions had been offered, *viz.*, that it was the result of tight bandaging; and that the child had had an attack of anterior poliomyelitis. The condition had developed within two weeks after the vaccination, and the power of motion in the arm had been largely recovered. There was no history of constitutional disturbance. His own opinion was, that the case is one of ascending neuritis involving the circumflex, ulnar, and musculocutaneous nerves.

PULMONARY TUBERCULOSIS AND TABES DORSALIS IN THE SAME PATIENT.

DR. FRAENKEL presented a man, thirty-nine years of age, unmarried, whose family history was negative. About ten years before he had contracted syphilis, but enjoyed fairly good health up to two years ago. At this time he had repeated hemorrhages from the lungs, and rapidly developed the signs and symptoms of pulmonary tuberculosis. On admission to the Montefiore Home, May, 1896, there were present pronounced physical signs of pulmonary tuberculosis, and of a large cavity at one apex, and death seemed imminent. The left pupil was but slightly responsive to light. The temperature never rose above 98.5° F., or the pulse above 80. He steadily improved up to May, 1897, at which time his sputum still contained tubercle bacilli, but his condition was in every way better. The signs of the cavity had disappeared. His pupils were unequal, and the left was myopic. The scapular, abdominal, gluteal, and plantar reflexes were exaggerated on both sides. The left patellar knee-jerk was markedly diminished. There was no evidence of ataxia or of incoordination. On November 18, 1897, physical examination showed the thoracic organs to be in about the same condition. The patient then complained for the first time of occasional shooting pains in the left lower extremity. The sexual appetite was markedly diminished. The left knee-jerk was greatly reduced. The three points of interest were: (1) The marked unilateral character of the symptoms; (2) the combination of tuberculosis and tabes —a very rare condition, and (3) the apparent mildness of both diseases.

DR. NOYES said that the case appeared to be one of fibroid phthisis. Non-progressive tabes is due rather to a collection of connective tissue than to any actual degeneration of the posterior columns. These two conditions are occasionally associated, and the case presented is probably an example of this.

TIC CONVULSIF.

DR. WILLIAM HIRSCH presented a young man having tic convulsif. The doctor had first seen him about a year ago, and the symptoms had not changed materially since then. The object in presenting the patient was to demonstrate a certain relation between his symptoms and the psychic condition present. On tapping the cheek, the patient makes a number of grimaces. The fact that the symptoms had not changed was in marked contrast with what is observed in hysteria. This patient had had articular rheumatism, followed by endocarditis and the development of mitral insufficiency. Shortly afterward he had developed the neurosis in question.

WRY-NECK AND ASYMMETRY OF THE FACE.

DR. GRAEME M. HAMMOND presented for DR. MEIROWITZ a boy sixteen years of age, who had come under observation for the relief of what appeared to be a wry-neck. As far back as could be remembered the head had been deflected to the left, but he had never experienced any pain in the neck or elsewhere. There had been no twitching or jerking. Examination showed that the head deviated to the left; the left half of the face exhibited a perceptible slope from above downward to the left eyebrow; the side of the nose, the angle of the mouth, and the angle of the jaw were all higher than the corresponding points on the right side. The muscles of the neck were distinctly hypertrophied. The skull over the parietal region showed a perceptible flattening, not observed on the other side. The movements of the head were free in all directions. The hair curved to the left side. There was no disturbance of the cranial nerves, and no hemiatrophy, and the intelligence was normal. There was no family history of similar defects.

DR. FRAENKEL remarked that cases of congenital wry-neck had been explained as resulting from a lessened developmental resistance on one side.

DR. ONUF said that in most cases of congenital wry-neck there is this asymmetry of the face. He was not sure that pressure is alone responsible for the unequal development; it would hardly explain the asymmetric development of the ear. The atrophy seemed to him to be possibly the result of twisting of the carotid artery on one side, with a consequent interference with the nutrition on that side.

ENORMOUS HYDROCEPHALUS.

DR. F. PETERSON presented the brain from such a case, one of the largest observed during many years at the Randall's Island Hospital. The patient was a woman of twenty years, who, in the early stages, had had a left hemiplegia and imbecility. As the disease progressed she became diplegic and completely idiotic. The following are the measurements of the head: Circumference, 63.5 cm.; approximate volume, 1714 c.cm.; naso-occipital arc, 47 cm.; nasobregmatic arc, 16.5 cm.; bregmatolambdoid arc, 19 cm.; binauricular arc, 50 cm.; anteroposterior diameter, 19.5 cm.; greatest transverse diameter, 18.5 cm.; length-breadth index, 94.8 per cent.; binauricular diameter, 12 cm.; auriculobregmatic radii, 20 cm.; facial length, 11.2 cm.; empiric greatest height, 17.7 cm.; height Beta-x, 19.2 cm. At the autopsy the sutures were found fully united and the fontanels perfectly closed. The skull-bones averaged 8 mm. in thickness. The dura in was not anywhere adherent. There was very little fluid the dura. Nearly all of the fluid was in the ventricles of the brain, there being more on the right side than on the left, for the right hemisphere had become in part membranous. Five pints of clear serum was removed from the ventricles. The third and fourth ventricles partook to some extent in the dilatation. It was unfortunate that through a mishap the brain was so injured that the patency of the foramen of Magendie could not be determined. Dr. Peterson said that, in his experience, it was difficult to examine this foramen, and apparently impossible to demonstrate the presence in any human being of the foramina of Mierzejewsky. It is very important in all cases of chronic hydrocephalus to examine, if possible, the foramen of Magendie, and not only that, but to determine the patency of of the aqueduct of Sylvius and of the foramen of Monroe. He had, with Dr. Blake, at the anatomic laboratory of the College of Physicians and Surgeons, examined the brain of a ten-year-old hydrocephalic of Randall's Island, and, in this instance at least, had determined definitely the permeability of the foramina mentioned, and also of the aqueduct.

ABSCESS OF THE BRAIN.

DR. PETERSON presented a specimen showing an abscess of the brain, operation having been attempted for its relief. The case had been first observed on September 3, 1897, in the service of Dr. Brown of the Mountainside Hospital, at Montclair, N. J. The patient was a male, forty-one years of age, who, in an attempt at suicide, had struck his head upon a rusty spike and had sustained a compound depressed fracture in the right occipital region, very near the middle line. He was trephined, and the depressed bone removed. The dura was found uninjured, and was not touched. The wound became slightly infected, but aside from moderate fever no symptoms of importance appeared until two days before he had first seen the man, *i.e.*, about two weeks after operation. He then gradually developed within twenty-four hours a left hemiplegia, with left hemi-anesthesia. Examination showed complete paralysis of the left arm and leg, with considerable anesthesia over the paralyzed limbs; slight analgesia in some places, and hyperalgesia in others. The plantar and cremasteric reflexes were normal. The knee-jerks were subtypical, slightly greater on the left side. The mind was clear. There was no aphasia, no involvement of the face or tongue. There was no evidence, in pupils or pulse, of intracranial pressure, and no symptoms of cortical irritation. The temporal half of the field of vision of the left eye was lost. The right seemed nor-

mal. He heard a watch at only half the distance with the left ear as compared with the right. Taste was normal on both sides of the tongue. The fundus seemed slightly cloudy. A diagnosis was made of abscess deep in the brain in the region of the posterior limb of the internal capsule. The surgeon was advised to trephine in the parietal region, considerably back of the motor area, and insert an exploring-needle down into the supposed site of the abscess should the patient grow worse. Two days later this was done. The abscess was found at the site suggested, and was drained. The temperature became normal, the anesthesia disappeared, and the patient moved his left hand; but a few days later he suddenly became worse and died. The brain was sent to Dr. Peterson for examination. He found the dura very sclerotic over the site of the original injury close to the superior longitudinal sinus. The convolutions of the right hemisphere were considerably flattened. There was no meningitis. Deep in the interior of the right hemisphere was an abscess about the size of a hen's egg.

HEMIATROPHY OF THE BRAIN.

DR. PETERSON then presented a specimen showing apparent hemiatrophy of the brain. The brain was that of a Randall's Island patient, a man thirty years of age, who had been in the idiot asylum for several years. A history of the origin of his trouble could not be obtained. He was a large, heavy man, with a hemiplegia (the arm being much worse than the leg), and had frequent and severe attacks of general epileptic convulsions. While able to be about, he was dull and stupid, and in intelligence would be placed in the grade of moderate idiocy. He died in an epileptic fit. There was nothing abnormal in the other organs of his body, but the brain presented the condition of marked right hemiatrophy. There was very slight evidence of microgyria, the convolutions differing as regards normality from those of the opposite side in being somewhat smaller. The membranes over the right hemisphere were, perhaps, somewhat thicker than over the left. An examination of the vessels at the base of the brain showed that the blood-supply was apparently equal on the two sides. It was undoubtedly a lack of development through some obscure and early pathologic process.

A CASE OF AMIATROPHIC LATERAL SCLEROSIS—SUPPLEMENTARY REPORT.

DR. WILLIAM HIRSCH said that on October 1, 1895, he had presented to the Society a case of this kind. The patient was forty-three years of age, and had had poliomyelitis at the age of twenty. The clinical symptoms were such that at that time they had been traced to an old scar in the left anterior horn in the cervical region. The process must have approached the left pyramidal tract, and then, after affecting the right horn, spread over the right pyramidal tract, causing a spastic condition of the right leg. In the discussion which followed the presentation of the case, it was claimed that it was one of ordinary progressive muscular atrophy. But further clinical observation showed that such was not the case. The man died June 3, 1897, and Dr. Hirsch was now able to present microscopic specimens of the spinal cord in different regions, proving the correctness of his diagnosis. He said that in these specimens one could see the connective tissue spreading from the anterior horn to the left pyramidal tract, and the latter converted into connective tissue. The cells in the anterior horns had been destroyed; the connective tissue had formed all through the lateral tract. In the cervical region one bundle of connective tissue had spread backward into the posterior columns, as he had previously diagnosticated. Deep degeneration of the pyramidal tracts could be followed down to the lumbar region.

DR. HAMMOND asked how he would differentiate these specimens from progressive muscular atrophy.

DR. HIRSCH replied that the specimens showed that the case was not one of ordinary degeneration of the lateral tracts, but that the connective tissue grew horizontally from the anterior horn to the side. Furthermore, ordinary progressive muscular atrophy is a symmetric disease.

DR. HAMMOND said that in three unquestioned cases of progressive muscular atrophy which had been under his observation, there had been a typical degeneration of the pyramidal tracts. On looking up the subject, he had found that Gowers made the statement that he had not seen a case of progressive muscular atrophy in which the pyramidal tracts had not been extensively affected. It is true that in the specimen presented, one horn is affected more than the other, nevertheless, both horns are involved.

DR. C. L. DANA thought the sections looked very much like specimens from a case of progressive muscular atrophy. If the pathologic change were not one of degeneration of the horns and lateral columns, he would like to know what Dr. Hirsch thought it really was.

THERAPEUTIC HINTS.

An Ointment for Mumps.—

℞ Ichthyol, Plumbi iodi aa . . . gr. xlviii
Ammon. chloridi . . . gr. xxx
Vaselini . . . . . ʒ i.

M. Ft. ung. Sig. Apply with friction over swollen glands three times daily.

To Allay Pruritus in Eczema of the Scalp the following is recommended:

℞ Ac. salicyl. . . . . gr. vi
Menthol. . . . . gr. xii
Ol. lini, Aq. calcis aa . . . . ʒ i.

M. Sig. For external use.—*Steinhardt.*

For Facial Erysipelas.—

℞ Ac. carbolici, Tr. iodi, Alcohol. aa . . . . 3 i
Ol. terebinth. . . . . 3 ii
Glycerini . . . . . 3 iii.

M. Sig. Paint over affected parts.

VOL. LXXII. NEW YORK, SATURDAY, JANUARY 29, 1898. NO. 5.

ORIGINAL ARTICLES.

THE PRESENT STATUS OF VAGINAL OPERATIONS FOR DISEASES OF THE PELVIC ORGANS.[1]

BY EDWIN B. CRAGIN, M.D.,
OF NEW YORK;
ASSISTANT GYNECOLOGIST TO ROOSEVELT HOSPITAL.

THE time has come for a careful revision of our experience with vaginal operations and a calm judgment of their utility. The new operation, so attractive to a large number of the profession, has gradually lost its newness, and with a considerable mass of evidence, *pro and con*, presented from different sections of this country and from abroad, we are now in a position to ask and answer the question: Are we better able to treat patients suffering with diseases of the pelvic organs now than we were before the resurrection and extension, under the stimulating influence of the French surgeons, of the operation tried years ago and abandoned by Thomas, Gilmore, Battey, and others?

By the vaginal operation is meant the direction of attack and procedure in different operations upon the pelvic organs—draining abscesses or inflammatory exudates; removing tumors, the uterus, or the appendages.

It is only natural that after years had been spent in perfecting technic and developing dexterity in the abdominal operation a change so radical as that involved in the vaginal method should meet with opposition. Objections, the operation has, and now after several years of experience with it, we know something of the objections, something of what the limits of the operation should be.

It is said that the vaginal operation is a difficult one, and this must be admitted even by those who favor vaginal work and use this route in a large proportion of their cases. It certainly requires more practice to become familiar with it than the abdominal operation; but here as elsewhere experience removes the difficulties and practice gives dexterity.

Certain dangers have been emphasized as being more marked in vaginal than in abdominal work. Of these, hemorrhage and injury to the neighboring viscera, with resulting fistulæ, have been made especially prominent. It must be confessed that there has been ground for criticism in the early work of almost all who have tried and practised the vaginal method, and occasionally one has been obliged to open the abdomen to check bleeding, the control of which he did not feel sure of from below. As experience has increased, however, and we have better learned to judge the class of cases suitable for vaginal attack, the control of hemorrhage has been found to cause little, if any, more trouble than in abdominal operations.

Rectal fistulæ during one's early experience with vaginal work occurs perhaps with rather greater frequency than when operating through a large abdominal wound with the patient in the Trendelenberg position. The differential feel between rectum and distended Fallopian tube is not always appreciated with ease. Even the entrance into the peritoneum through the posterior vaginal fornix, in one's early work, sometimes gives trouble, especially when the pouch of Douglas is obliterated by adhesions, and in our efforts to separate these adhesions the rectum has been injured. Experience and the selection of cases suitable for the method have helped largely to overcome this complication, and it is generally conceded that even if a fistula does occur, as a rule, it closes spontaneously in a short time.

Thus far we have spoken chiefly of the disadvantages of the method and of its complications. Why should one wish to employ the vaginal operation if it is more difficult for the operator? Because we believe that in properly selected cases the operation is accompanied by less shock, the mortality is less, the convalescence is smoother, and even if the occurrence of hernia in a properly conducted abdominal operation is rare, it must be admitted that in the vaginal method it is still more rare; the writer has never met with one in his own experience. Although the avoidance of an abdominal cicatrix is not a matter of great importance, if the operation can be equally well performed without one, it is usually appreciated by the patient. The rapidity of convalescence and the shortness of time which the patient is required to be kept in bed are sometimes emphasized by enthusiastic advocates of the vaginal operation; but in the opinion of the writer, although the patients feel like getting out of bed sooner than in the abdominal operation, they should not be allowed to do so for at least two weeks. A firm cicatrix, absorption of exudate, and the future welfare of the patient

[1] Read at the Ninety-second Annual Meeting of the Medical Society of the State of New York, held at Albany, N. Y., January 25, 26, 27, 1898.

are certainly more promoted by rest and quiet than by any attempt to see how early the patient can leave the bed.

In certain cases the vaginal operation has marked advantages, and in our discussion of the subject the most important feature is the selection of cases for which the operation is suited. The writer, on looking over the record of his vaginal work, found included in the list, aside from operations for the removal of the uterus and appendages, such operations as removal of the vermiform appendix, removal of a displaced left kidney, myomectomy at the fundus of the uterus, etc. Certainly the possibilities of the vaginal method are great, but the question before us as conscientious surgeons is not what *can* be done through the vagina, but what, in the interest of the patient, *can best* be done in this way.

It is only natural that in testing the merits of a new operation we should extend its use into fields whose boundaries riper experience tells us had better not be crossed. In my early vaginal work a number of patients were operated upon by this route in which the uterus appeared to be so healthy that its removal did not seem indicated in spite of the removal of both appendages. Although the results were good, experience and observation lead me to think that, except in the case of small ovarian tumors, *if the uterus is not to be removed*, the abdominal operation is to be preferred for the removal of one or both appendages. Small ovarian cysts and prolapsed diseased ovaries, requiring removal, form a class of cases often well adapted to the vaginal operation. Except in these instances, however, I believe that unilateral disease of the appendages is best dealt with from above, where the organs may be more thoroughly inspected, and those which are not to be removed may be left in the best possible condition for the future welfare of the patient. These are general rules, and many exceptions may occur. A woman with a roomy vagina and a thick, fat abdominal wall, with the mass to be removed lying low in the pelvis, is a favorable subject for vaginal work.

The vaginal operation has been tried in different phases of ectopic gestation, but experience proves that except in cases in which rupture has taken place some time previously and the resulting hematocele is well encapsulated, the abdominal operation is the one to be preferred. Many operations have been tried through the vagina for the correction of posterior displacements of the uterus, but on account of frequent dystocia among those in whom pregnancy has followed the operation, vaginal fixation of the uterus has been largely abandoned. Vaginal shortening of the round ligaments at present has rather a brighter outlook, but experience with it has been so limited that judgment must be reserved.

Into the general question of whether it is advisable after resection of a portion of a diseased ovary or tube to leave the remainder, if apparently healthy, I shall not enter, but will only say that if this conservative work upon the appendages is to be done, most operators are agreed that it is better done from above than from below.

A class of cases in which the vaginal operation has proved of great service to the writer comprises women who are pregnant and whose parturient canals are obstructed by tumors which cannot be raised out of the pelvis. I have three times observed this condition, and by vaginal removal of the tumor have enabled the patient to be delivered of a living child.

There are three groups of cases in which the vaginal operation has proven, in my experience, a great boon to suffering women:

1. Pus cases in which removal of the uterus and appendages is indicated.
2. Cases in which exudate indicates drainage without the removal of any organ.
3. Small fibromyomata.

The question of whether hysterectomy is indicated in every double salpingo-oophorectomy will not be discussed in this paper. Suffice it to say, that the profession are pretty generally in accord that there are many cases of double pyosalpinx in which the uterus, enlarged, the seat of a marked endometritis, perhaps with cervix lacerated, had better be sacrificed if both appendages are removed. Experience seems to justify this conclusion, and it is just in these cases in which the vaginal operation, with its lessened shock, lessened handling of the intestines, and more complete drainage, finds its most perfect adaptation.

Puerperal septicemia does not often indicate hysterectomy, but there are a few cases, which, in the latter part of the puerperium, about the end of the first month, present pus foci in the uterine walls or in the appendages, or in both together. Here again vaginal hysterectomy has found a useful field. The writer has operated upon four such patients, saving two and losing two, a better result, I believe, than would have been obtained by the abdominal operation.

It has long been a familiar fact that patients profoundly septic do not endure extensive operations well; and it has long been the practice of many men, in cases in which there are large collections of pus, to drain the abscesses through the vagina and wait until the patient recovers from her sepsis before subjecting her to the radical operation. This certainly is a rational procedure, and its adoption has saved many lives by requiring, at a later date, a less

extensive operation than would have been needed early, and sometimes by obviating the necessity of a subsequent operation.

Thanks to the work of Henrotin of Chicago, we have found that in the relatively acute cases, before the formation of much or any pus, a great deal may be accomplished by vaginal incision, breaking up the adhesions about the appendages, and draining freely through the vagina. In one case, in which was threatened an extensive peritonitis from infected, retained secundines, the writer, by curettage of the uterus, vaginal incision, separation of the adhesions about the appendages, and free vaginal drainage, secured a rapid convalescence with no permanent damage to the tubes and ovaries. Two patients with pelvic peritonitis and exudate in the pouch of Douglas and about the appendages, with physical signs as nearly alike as two cases could be, were placed by me in adjoining beds in a hospital ward. In one a vaginal incision was made in the posterior fornix, adhesions were broken up, and the pelvis was drained with gauze; the other was subjected to the usual routine treatment of vaginal douches, boroglycerid tampons, and counter-irritation. The former patient convalesced and left the hospital in just about half the time required by the latter. Of course it cannot be proven that the two cases were absolutely alike, but the symptoms and physical signs resembled one another closely, and the rapid symptomatic cure in one by means of drainage was in marked contrast to that of the other. The writer would not be understood as recommending vaginal incision in every case of pelvic peritonitis, but when there is present evidence of fluid exudate in the pelvis, vaginal incision and drainage will, I believe, shorten the convalescence and lessen the damage to the appendages.

Whether fibromyomata of the uterus should be attacked through the vagina depends upon their size and location in the uterus. If myomectomy is to be performed, unless the tumor is situated in the lower uterine segment, or in the cervix, the abdominal route should have the preference. If hysterectomy is to be done, and the uterus and tumors together do not form a mass larger than a pregnant uterus of three or four months, the vaginal operation, with or without morcellation, has advantages so marked that one has only to watch the convalescence in such cases to be impressed with the fact that patients thus operated upon present but little more reaction than from a plastic operation for the repair of cervix and perineum.

Into the technic of the operation I shall only go far enough to emphasize the value of (1) morcellation, (2) the Mikulicz drain, and (3) ligatures. Those who have not tried and practised morcellation in some form or other in the course of a vaginal hysterectomy with an enlarged uterus, have certainly not availed themselves of their opportunities. The facility which is thus given the operator in acquiring needed space for work, and in reaching parts hitherto beyond his reach can only be appreciated by those who have tried it. In the case of a fibroid uterus, with pus in tube or ovary, morcellation proves of especial value; as, after the removal of the cervix and middle third of the uterus, and the splitting of the fundus, the fingers, or even the hand if it is small, may be introduced into the pelvis and the appendages enucleated. It is probably familiar to nearly all that the secret of success in morcellation lies in the fact that steady traction upon the uterus, with a reliable volsella affixed above the part to be removed, controls hemorrhage.

In all cases requiring drainage after vaginal hysterectomy, the principle of the Mikulicz pouch carried out in the following manner has given me most excellent service: A square handkerchief-shaped piece of gauze is opened out by an assistant and held in front of the vulva; a blunt instrument, like a sponge-holder is placed by the operator against the center of this gauze and pushed on into the pelvis. The fingers of the operator are now substituted for this instrument and carried up on one side until he feels that he is above the highest pedicle of that side. The end of a long narrow strip of gauze is then passed along the finger, of course within the pouch, until it too is carefully placed above and against the highest pedicle; enough of the same long narrow strip is inserted to loosely fill that half of the pelvis. The fingers are then introduced above the pedicles on the other side and the same process repeated either with a part of the same long strip or with another. In this way the intestines are kept away from the field of operation, drainage is secured, and the strip of gauze may be gradually withdrawn from the pouch with scarcely any disturbance to the patient; the pouch collapses as its contents are removed and may be withdrawn as desired.

The profession is divided in the choice of clamps or ligatures as a means of controlling hemorrhage. It undoubtedly is often a great convenience to use clamps at various stages of the operation, but the impression seems to be gaining ground that the comfort of the patient is better provided for if the clamps, when used, are replaced by ligatures before the patient leaves the table. In my own practice it is a very rare exception if clamps are left on when the patient leaves the operating-room.

In conclusion we believe:

1. That there are many conditions in the pelvis not suited for the vaginal operation.

2. That care is required in the selection of cases for this work.

3. That small fibromyomata and small ovarian tumors are often well suited for vaginal attack.

4. That in pus cases indicating hysterectomy, and in cases requiring drainage, the vaginal operation has great advantages.

5. That in answering the question presented at the beginning of this paper we must admit that we are much better able to treat and cure patients suffering with disease of the pelvic organs now, than we were before the development of the vaginal operation.

OTITIS MEDIA PURULENTA; ITS COMPLICATIONS AND TREATMENT.[1]

BY GORHAM BACON, M.D.,
OF NEW YORK;
PROFESSOR OF OTOLOGY IN THE NEW YORK UNIVERSITY MEDICAL COLLEGE; AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

I SHALL only endeavor, in the short time before me this evening, to refer in a general way to the more important symptoms of purulent otitis media, both acute and chronic, and to the complications of this disease. The subject is such an inexhaustible one that it will only be possible to touch on a few of the most important points. The causes of acute purulent otitis media are cold, influenza, the exanthematous diseases, diphtheria, typhus and typhoid fever, bronchitis, cerebrospinal meningitis, pneumonia, tuberculosis, the puerperal state, syphilis, sea-bathing, injuries to the auditory canal and drumhead from blows, falls, the improper use of instruments, and the application of caustic solutions. The use of the nasal douche, and sniffing up of salt and water for nasal catarrh, frequently cause otitis media. Dentition plays an important rôle, as children during this period very often have acute otitis media which subsides after the eruption of a tooth. Adenoid growths and enlarged tonsils should also be mentioned among the causes of this disease. As a rule, this form of inflammation begins in the nasopharynx and extends by means of the Eustachian tube to the middle ear.

Scarlet fever, measles, diphtheria, and influenza are responsible for most of the cases of acute as well as of chronic otitis media, so that it is of the greatest importance that the ears should be frequently examined during the course of one of these diseases. Prompt and early treatment will often effect a cure. Neglect of treatment, or "letting the ears take care of themselves," results, as a rule, in chronic purulent otitis media with caries of the ossicula and other complications. Besides pain and tinnitus there is present more or less febrile disturbance until rupture of the drumhead occurs. The temperature in children is apt to be very high, and the commencement of an attack is sometimes ushered in by a convulsion or severe vomiting, so that a diagnosis of meningitis has occasionally been made in such cases. In the tuberculous form, perforation of the drumhead occurs without pain, and in such, the drumhead and middle ear are, as a rule, quite pale in color.

The pain, after the discharge appears, is usually much less severe, and children who a short time before were screaming on account of its severity, suddenly fall asleep, while the temperature is apt to drop several degrees. When the pain persists after the ear has begun to discharge it is probable that the periosteum of the external meatus or the mastoid cells are involved. The most frequent seat of perforation is in the lower anterior or posterior quadrant, although in some instances it is observed in Shrapnell's membrane. The inflammation is apt to be of a much more severe type and run a more protracted course in patients who are scrofulous, or who have, or have recently had, scarlet fever, measles, diphtheria, or influenza. Acute purulent otitis media may terminate in recovery with or without permanent loss of hearing, or may become chronic.

It is most important in the acute inflammatory stage of purulent otitis media to at once apply the artificial leech close to the tragus, and thus endeavor to abort the disease by antiphlogistic measures. If, in spite of this treatment, the pain persists, or bulging of the drumhead occurs, we should at once make a free incision in the drumhead, but never a small opening with a paracentesis needle, as was formerly advised. A physician should never incise the drumhead unless he is able to see the membrana tympani by means of a good illumination with head mirror and speculum. During the course of scarlatina, measles, diphtheria, influenza, typhus, and typhoid fever, the ear should be constantly examined, and as soon as it is evident that there is fluid in the tympanic cavity it should be at once evacuated by means of a free incision in the drumhead. It should be the object in all cases in which micro-organisms are present in the discharge to use antiseptic solutions (preferably the bichlorid of mercury, 1–3000). The same treatment should be applied to the nasopharynx and nares by means of an atomizer. It should then be the endeavor to drain the middle ear as thoroughly as possible, and for this purpose, in addition to irrigating the canal, a strip of iodoform gauze should be pushed down to the drumhead and renewed as often as necessary.

If a free incision is not made and proper drainage from the middle ear established, there is then great

[1] Read at a meeting of the New York Academy of Medicine, December 2, 1897.

danger that the acute purulent otitis media will become chronic. The pus not having a free exit forms caseous masses in the attic and antrum, and caries of the ossicles and inflammation of the mastoid cells is the result. In that form of inflammation limited mostly to the attic and Prussak's spaces, it is imperative, during the early stage, that several incisions should be at once made in Shrapnell's membrane, otherwise the pus cannot escape, and will be apt to cause caries of the ossicula, and the disease thus becomes chronic. When the latter condition results the surgeon should endeavor to thoroughly drain the cavity by enlarging the opening, if this be too small, and to wash out by means of the middle-ear syringe all secretion in this part of the tympanic cavity. Here bichlorid of mercury solutions are again indicated. Granulations should be destroyed by applications of chromic acid or by the use of curettes. If in spite of local treatment the discharge continues, a cure may undoubtedly be effected in a certain number of cases by excision of carious ossicles and remains of the drumhead, and by scraping and curetting the attic. There are, however, a large number of cases of long-standing suppuration in which removal of the ossicles will not effect a cure, and in such it becomes necessary to cut down on the antrum, from behind the auricle, and perforate the bone with chisels and mallet. Thus, the antrum may be reached and cheesy matter, which so often collects in this cavity, may be removed.

As a result of the acute and chronic forms of otitis media the following complications are liable to occur: Granulations and polypi; caries of the ossicula and temporal bone; cholesteatoma; mastoid disease; suppurative meningitis; epidural abscess; cerebral abscess (temporo-sphenoidal and cerebellar); pyemia; septicemia, and facial erysipelas. I have reported two cases in which facial erysipelas was secondary to acute otitis media. In both patients the general health was impaired. Disease of the mastoid cells may occur as a sequel of acute otitis media purulenta, or may develop in connection with the chronic form of the disease. There have been, according to my experience, many more cases of mastoid disease since influenza made its appearance in this city. It was formerly the exception for the mastoid cells to be simultaneously involved in a case of acute otitis media. Of late years this condition of affairs has been very frequent.

If, during the course of acute otitis media, the temperature remains high after the drumhead has been incised and the mastoid cells opened, the possibility of the existence of a latent pneumonia, or of some other complication, especially sinus thrombosis, should be considered. I have recently observed two cases in which pneumonia was the cause of the high temperature. I have also reported a case of acute otitis media and mastoid disease in which the temperature was very high and remained so until four molar teeth made their appearance. When mastoid disease exists, the temperature may vary from 99.5° to 104° or 105° F. As a rule, the temperature in simple uncomplicated cases is lower in adults than in children. A patient with extensive caries of the mastoid cells and with a carious opening into the cranial cavity may have a temperature but slightly above the normal, so that a comparatively low temperature does not necessarily signify that the case is not one of considerable gravity. Teething infants may present a temperature of 105° F., which is due to an otitis media. Puncture of the drumhead will cause a drop of several degrees in the temperature. When the perforation closes too suddenly the fever is apt to recur. In a case of measles in which both drumheads were bulging and tenderness on pressure existed behind the mastoid, with a temperature of 104° F., a free incision in both drumheads caused the temperature to suddenly fall to 100° F. An operation on the mastoid process should never be deferred until redness and edema of the tissues over the mastoid have appeared and the auricle stands out prominently from the head.

If a patient is observed who has had an acute purulent otitis media for at least a week or ten days, and an examination shows a bulging of the upper wall of the auditory canal and drumhead, and there is pain on pressure over the mastoid antrum or tip, and, further, if there is some elevation of temperature (frequently very slight), and especially if there is a profuse discharge, these symptoms, taken together, are very characteristic of mastoid inflammation. The condition of both mastoid processes should always be compared, because in some persons pressure made over the normal mastoid will cause pain. Edema and swelling of the tissues over this bone and pain on pressure also occur in cases of furuncle of the external meatus; an examination of the auditory canal will, of course, exclude this.

When acute inflammation of the mastoid cells occurs in connection with chronic purulent otitis media it is usually advisable to at once open the cells; otherwise some more serious complication may develop, such as lateral sinus thrombosis or cerebral abscess. In the first stage of secondary mastoid inflammation, after a free incision has been made in the upper and posterior portion of the membrana tympani, the artificial leech should be applied just over the antrum and tip. The Leiter coil should then be immediately adjusted, as cold is one of the

best means of reducing the inflammation. The coil should not be left on longer than forty-eight hours, for, if at the end of that time the pain persists and other symptoms of mastoid disease are present an immediate operation is advisable. Just here I cannot too strongly protest against the frequent use of blisters for these conditions, a practice which only tends, I think, to aggravate the trouble. When an operation has been decided upon, a long incision should be made close to the auricle and extending from the mastoid tip to the upper border of the pinna, so that the entire mastoid process may be inspected. This incision may be enlarged in different directions if an intracranial complication exists. In acute cases it is not always necessary to remove the entire cortex, for the disease may be limited to one portion of the mastoid cells. It must not be forgotten, however, that when pus is not found in the antrum and upper part of the mastoid it may be contained in the tip. In such cases perforation of the tip frequently occurs, and if an operation is not immediately performed the pus will burrow down the neck beneath the deep fascia and possibly give rise to septicemia or pyemia. In all cases of mastoid disease occurring in connection with chronic purulent otitis media, the entire outer wall of the mastoid process should be removed and every pneumatic cell explored.

I sometimes inflate the ears by means of Politzer's method, when the perforation in the drumhead is large and the more acute symptoms have subsided, in order to remove the secretion from the middle ear. It is much better, however, to use a catheter if only one ear be affected, for fear of forcing pathogenic organisms into the normal ear. When caries of the tympanic roof has occurred, a collection of pus is frequently found between the bony wall and the dura, or this complication may be followed by an abscess in the temporo-sphenoidal lobe of the brain. In mastoid disease it is quite common to find erosion of the bony wall just over the lateral sinus, the sinus embedded in pus, and granulations or an abscess may be found in the cerebellum. Cases of extradural abscess are much more frequently observed than abscesses in the temporo-sphenoidal lobe or cerebellum. Cerebral abscess almost always occurs in connection with chronic purulent otitis media, although I have reported one case of temporo-sphenoidal abscess which followed acute otitis media.

The first stage of abscess is usually marked by irregular symptoms, such as irritability, pain, nausea or vomiting, and frequently the discharge from the ear becomes scanty or stops altogether. The occurrence of a change in a patient's disposition, *viz.*, a talkative person becoming morose, or *vice versa*, is another symptom of importance. The patient frequently complains of chilly sensations. As the disease progresses the cerebration becomes dull and the patient appears stupid and restless. When pus has formed in the brain the most important symptoms are a distinct lowering of the pulse-rate and a temperature either slightly above normal or subnormal. There are exceptions to this rule, for I have reported a case of temporo-sphenoidal abscess in which the pulse was rapid and the temperature very high, with marked fluctuations, so that thrombus of the lateral sinus was suspected.

When aphasia develops in a patient with a chronic purulent otitis media of the left side, it is fairly certain, if the patient be right-handed, that there is a collection of pus in the temporo-sphenoidal lobe. I believe this symptom to be of the greatest diagnostic value—optical aphasia, so-called and described by Freund, Pick, and Starr. Severe headache is also usually an important symptom. Inflammation of the optic nerve may or may not be present. It is more frequently observed in cases of cerebellar than of temporosphenoidal abscess. The mastoid cells are often found to be dense and ivory-like in cases of cerebral abscess. This seems to me an important point, for in such the pus is likely to perforate the tympanic roof, and thus cause an extradural abscess or an abscess in the temporo-sphenoidal lobe. Percussion of the skull on the affected side frequently causes pain, and Macewen has called attention to the fact that there is a difference in the percussion note on the side of the head in which the abscess is located. Other symptoms sometimes noticed are digestive disturbances, increase of reflexes in the limbs of the side opposite to the abscess, a difference in the size of the pupils, and facial paralysis.

In cerebellar abscess, the most characteristic symptoms besides slow pulse and low temperature are severe headache, nausea, vomiting, vertigo, a staggering gait, and facial paralysis. Facial paralysis may be due to pressure on the facial nerve in the pons. It must also be remembered that the nerve may be affected in its course through the middle ear. I have observed a case in which the pulse was slow and the patient had vertigo, vomiting, deafness, severe headache, etc., so that a diagnosis of cerebellar abscess was made. When the antrum was opened the semicircular canals were carious, which fact accounted for the symptoms. It is very important to thoroughly examine the external auditory canals in all cases of suspected cerebral abscess; for instance, in the case of a child who was brought to my clinic a short time ago, and who had characteristic symptoms of cerebellar abscess, including choked discs with retinitis, removal of granulations from the

middle ears, with the establishment of proper drainage effected a cure. The choked discs and retinitis disappeared.

When thrombosis of the lateral sinus exists, the more prominent symptoms are severe headache, high temperature with decided fluctuations, nausea, vomiting, and rigors. Over-distension of the superficial veins in the mastoid region, with swelling of the tissues around the mastoid tip, are sometimes observed. When the internal jugular becomes involved there will be tenderness on pressure along the course of this vein, and it will also present a cord-like feel. Some of the deeper veins of the neck may also become thrombosed. At a late stage the cervical glands sometimes become enlarged. When an operation is postponed too long, pulmonary infarctions develop which in the early stage do not give rise to physical signs, and also general infection results; hence, the occurrence of septicemia and pyemia.

In all cases of brain complication, due to acute and chronic otitis media, the surgeon should first of all open the mastoid antrum and make this the starting-point of the operation; for it is in this cavity that the micro-organisms exist and where they rapidly fructify as long as the soil is fertile. Antiseptics injected into the middle ear do not reach them. The various cocci and bacilli found in the nasopharynx enter the tympanic cavity through the Eustachian tube. It is possible, however, for a purulent discharge in the ear to escape into the nasopharynx and cause a pneumonia, or if swallowed, the patient may have as a result a foul-smelling diarrhea.

The tympanic roof should be explored for a carious opening. If found, this should be enlarged and the bone just above the antrum cut away with forceps so that the dura in the middle cranial fossa may be thoroughly explored. From this point an exploring-needle may be introduced into the temporo-spenoidal lobe if brain abscess be suspected. If the symptoms point to thrombus of the lateral sinus, the latter may be quickly exposed by cutting away the bone with chisels and forceps. In some cases a thrombus will be found in the sinus even when a needle has been introduced and fluid blood withdrawn, and also when the sinus pulsates. In such cases, it is necessary to open it with a bistoury. This may be done if everything required to plug the sinus in case of hemorrhage be at hand. If the indications point to abscess in the cerebellum, the sinus should always be first uncovered, and then the opening may be enlarged posteriorly and the cerebellum explored for pus.

The question of ligating the internal jugular vein, whenever a thrombus is found in the latter, is a point still unsettled. My own opinion is that it is unnecessary to do this if it is possible to establish a free flow of blood in each end or the divided sinus. Pressure should be made on the neck from below upward along the course of the internal jugular vein in order to remove any thrombi in the lower end of the lateral sinus. A probe should be passed to the torcular and jugular bulb if necessary. If the flow of blood cannot be reestablished from the lower end of the sinus, it then becomes necessary to ligate the internal jugular vein, especially if there be tenderness or a cord-like induration along the vein. For fear of injuring some vessel in the brain it is better to use an instrument devised by Horsley rather than a sharp-pointed exploring-needle. I have never seen any bad results from exploring the different parts of the brain, if the operation is carefully performed and under strictly aseptic conditions.

All operations on the cranial cavity should be performed at an early stage of the disease if we wish to meet with success, and as rapidly as possible, for in many instances, I believe that patients are anesthetized for too long a time. I use the burrs recommended by Macewen in some cases, but, as a rule, I find that I can work more quickly with gouges, drills, and forceps. After evacuating the pus in a brain abscess great care should be exercised in syringing the cavity. A boracic-acid solution should be used, and afterward iodoform gauze loosely packed in the cavity. I prefer the gauze method of draining the abscess cavity to the use of drainage-tubes. In some cases in which the mastoid process is sclerosed, it will be necessary to remove a button of bone with the trephine in order to perform the operation as speedily as possible.

THE EARLY DIAGNOSIS AND TREATMENT OF EXTRA-UTERINE PREGNANCY.

BY G. H. BALLERAY, M.D.,
OF NEWARK, N. J.;
GYNECOLOGIST TO THE PATERSON GENERAL HOSPITAL AND TO ST. JOSEPH'S HOSPITAL, PATERSON, N. J.; OBSTETRICIAN TO THE MATERNITY HOSPITAL, PATERSON, N. J.

UNTIL within the last fifteen years extra-uterine pregnancy was considered to be of such rare occurrence that most practitioners did not think it worth while to study the signs and symptoms which indicate the presence of this condition. Of late, however, a growing interest is being manifested in regard to its cause, diagnosis, and treatment. The cause of ectopic pregnancy is admitted to be some abnormal condition of the Fallopian tube, and it is generally conceded that almost all cases of extra-uterine gestation are primarily tubal—the almost endless variety described by the older writers being but accidental modifications of tubal pregnancy. We are indebted to Lawson Tait for the elucidation of

this subject, and I think it may be truthfully said of him that he has accomplished more than any other man in placing the pathology of extra-uterine pregnancy upon a rational basis. Not only has he clearly pointed out the pathology of ectopic pregnancy, but by example he has taught us how to successfully treat this serious condition. My remarks will be limited to the diagnosis and treatment of extra-uterine pregnancy in the early months; its diagnosis and treatment at, or after, full term is so thoroughly considered in several classic works that it would be useless to repeat it here. Moreover, my personal experience in this class of cases is limited to a small number, and does not entitle me to treat the subject from a practical standpoint. The diagnosis of ectopic pregnancy in the early months, before the rupture of the sac, may present considerable difficulty, but that it is impossible, as some writers have claimed, is very far from true. I do not claim to possess any special diagnostic skill, and yet I have been able to diagnose extra-uterine gestation at this time on several occasions—the diagnosis in each case being verified by abdominal section. In this connection the two following cases may be interesting:

Case I.—Mrs. W., aged twenty-seven years, the mother of one child, nine months old. I was called to see the patient by Dr. Vroom of Ridgewood, N. J., on March 7, 1896. The patient's previous pregnancy had terminated during June, 1895, the only thing abnormal being that she flowed considerably at the time, and continued to lose a good deal of blood during the two subsequent weeks. After the birth of her child she did not menstruate until December 8, 1895. The flow continued nearly ten days and was rather profuse. The next menstrual period occurred January 8, 1896, and continued about the same length of time. Her third period came on March 6, 1896, and continued until I saw her on the 17th. The flow was at times rather profuse, and was accompanied by colicky pains in the abdomen, which were occasionally so severe as to require the use of morphin in moderately large doses.

The patient was very pale and anemic, and her pulse was rather frequent and soft; but she looked bright and cheerful and seemed to think that both her medical attendant and her husband were unnecessarily anxious in regard to her condition. On vaginal examination, I found the cervix enlarged and soft and the os uteri patulous.

The uterus, by conjoined manipulation, was found to be crowded over to the right side of the pelvis by a resilient mass situated to the left, and posterior to the uterus. The mass seemed to be about the size of a duck's egg and was not movable. The conclusion reached was that the case was one of left tubal pregnancy—the tube being firmly bound down by pelvic adhesions. I stated my opinion to Dr. Vroom, and urged the necessity of the immediate removal of the patient to the hospital, in order that she might be operated upon without delay should rupture of the sac occur. The patient's husband, an exceptionally intelligent man, having been informed of the nature of the case, took measures to have her carefully removed the same afternoon to the Paterson General Hospital, the understanding being that I would operate upon her as soon as she had recovered from the fatigue of the journey—probably within forty-eight hours.

The following day Dr. Henry C. Coe of New York saw the case in consultation with me, and concurred in the diagnosis and the propriety of an early operation. Accordingly, assisted by my colleague, Dr. I. L. Leal, and in the presence of Drs. H. C. Coe, Wm. Blundell, E. J. Marsh, and others, I opened the abdominal cavity. The left Fallopian tube, the seat of an ectopic gestation, was found to be greatly enlarged and bound down by adhesions to the posterior face of the broad ligament, and also to the rectum and small intestines. The adhesions were carefully broken down, and the mass ligated and excised. On examination, the right tube was found dilated into a sac about two inches in diameter, but free from adhesions; it was also removed. On subsequent examination it was found to contain a fetus which had probably reached the tenth week of development. The pelvic cavity was carefully cleansed, a glass drainage tube inserted, and the abdominal wound closed. The patient suffered severely from shock for about eighteen hours. She then began to rally and made an excellent recovery.

The points of interest in this case are as follows: (1) That it was a case of double extra-uterine pregnancy; (2) that the diagnosis was based upon the physical signs alone, the history being entirely negative, and (3) the evident advantage of the use of the drainage-tube. The presence of the drainage-tube enabled me to correctly interpret the symptoms which the patient presented a few hours after operation. These symptoms were extreme pallor, and coldness of the surface, including the face, very rapid and feeble pulse, widely dilated pupils, and sighing, almost gasping, respiration, with constant restlessness. The "air-hunger" was marked. A careful examination of the drainage-tube showed that there was no hemorrhage, only a moderate amount of bloody serum being discharged. The treatment consisted in keeping the foot of the bed elevated, application of warmth to the surface, administration, *per rectum*, of hot saline solution containing a large proportion of brandy, and the hypodermic injection of strychnin and enough morphin to allay restlessness. Under this treatment the shock gradually passed away, and the patient rapidly progressed toward recovery. So strongly did the symptoms point to the occurrence of hemorrhage that had it not been for the presence of the drainage-tube I should have been sorely tempted to reopen the abdomen, and such a course would in all probability have resulted fatally.

CASE II.—I was called on the evening of March 31, 1896, by Dr. Homer Sylvester, then House Surgeon at St. Joseph's Hospital, Paterson, N. J., to see Mrs. R., a ward patient, admitted a few hours previously. Dr. Sylvester informed me that he thought the case one of ectopic pregnancy. The patient was a poorly nourished woman, thirty-two years of age, the mother of five children, the last child being two years old. She had last menstruated normally three months previously. She had then gone over two months without any menstrual flow. Three weeks before admission to the hospital she began to have a slight bloody discharge from the vagina, attended by colicky pains in the lower part of the abdomen. The pains and bloody discharge would occasionally cease for two or three days and then recur and continue three or four days. At no time was the pain sufficiently severe to confine her to bed, and the bloody discharge was never profuse. At times the blood which escaped from the vagina was clotted, and the patient thought she had noticed a shreddy substance in the clots expelled. Her pulse varied from 86 to 94 per minute, and was soft and compressible; the temperature was 99° F. Physical examination disclosed a mass to the left, and posterior to the uterus; it was not movable and displaced the uterus slightly upward and to the right. By means of conjoined manipulation the body of the uterus was found somewhat enlarged. The cervix was enlarged and presented that peculiar softness which is the rule in the early stages of pregnancy. A diagnosis of extra-uterine pregnancy was made.

From the immobility of the mass, I was satisfied that the Fallopian tube, the seat of the ectopic gestation, was firmly bound down in the pelvis by adhesions. As it was late in the evening, and as I had several important engagements for the following day, I fixed on the day after for operation, it being understood that Dr. Sylvester should at once notify me should symptoms of rupture occur in the meantime. At 9.30 A.M. on the the morning of April 2, 1896, I went to the hospital prepared to operate. I learned that about four hours previously there had been an unfavorable change in the patient's condition. She had been seized with pain in the lower part of the abdomen, and shortly after the pulse became much more frequent than it had been before. I found her with a pulse of 120, lips somewhat blanched, temperature 98° F., and complaining of some pain in the abdomen. I concluded that the fetal sac had ruptured, and that a moderate hemorrhage into the peritoneal cavity had occurred. Stimulants and anodynes having already been administered, and the field of operation having been prepared, the patient was anesthetized and taken to the operating-room. With the assistance of my colleague, Dr. Jas. W. Smith, and in the presence of the hospital staff, I opened the abdomen. About a quart of blood (fluid and clotted) was found in the peritoneal cavity. The fetal sac, except at the point of rupture, was adherent to the rectum, small intestine, and posterior surface of the broad ligament. The adhesions were carefully separated and the sac removed. As the right ovary and tube were diseased, they were removed. The peritoneal cavity was flushed with a hot saline solution and thoroughly cleansed. A glass drainage-tube was then inserted, and the abdominal wound closed. Under the influence of stimulating enemata, the patient reacted well. The drainage-tube was removed on the third day, and the patient left the hospital in good condition at the end of the fourth week.

The points of interest in this case are: the typical history; the diagnosis before rupture, and the emphasizing of the importance of prompt action as soon as the diagnosis is made.

Under less favorable conditions, the loss of time which occurred in this case between the diagnosis and the operation might have resulted disastrously. On subsequent examination the fetal sac was found to contain both fetus and placenta, together with a small amount of clotted blood.

It is highly important that the physician engaged in general practice should be fully alive to the comparative frequency of extra-uterine pregnancy. He will then be on the alert, and will not be liable to overlook the condition simply because it does not present the whole array of classic symptoms. It is he who generally sees the case first, and upon his early recognition of its true nature will often depend the issues of life or death.

Some idea of the comparative frequency of ectopic pregnancy may be gathered from the fact that according to the records of the Paterson General Hospital (which as its name implies is a general hospital, and not a special institution for women) seven women have been operated upon for ruptured tubal pregnancy during the past eight months. These were all cases of rupture into the peritoneal cavity. A case in which rupture occurred between the layers of the broad ligament was also admitted during this period. This patient was not operated upon, and she recovered. During the past year, within a single month, the writer operated successfully in three cases of tubal pregnancy, and within a few weeks thereafter saw, with two medical gentlemen of large experience, two other patients who were actually moribund when first seen, and were, therefore, not operated upon. In neither case had the physician in attendance suspected the true nature, although the symptoms in both, as described by the medical attendants, were almost pathognomonic.

Diagnosis.—The diagnosis of ectopic pregnancy in the early months, before rupture of the fetal sac, is based upon the history and the physical findings. In a certain proportion of cases the history is such as to create a strong presumption in favor of the presence of this condition; on the other hand, the history is

often misleading, and in a large proportion of cases there is absolutely no history beyond the fact that the woman presented the usual symptoms of pregnancy and believed herself to be normally pregnant. In the latter case rupture of the sac is the first indication that anything abnormal exists. This terrible accident may then suddenly occur absolutely without premonition. It was formerly believed that extra-uterine pregnancy occurred almost invariably in women who had previously been sterile; *i. e.*, who either had never been pregnant or had not borne a child for a long period prior to the occurrence of the abnormal gestation. That sterile women are more likely to become subjects of extra-uterine pregnancy than those who have frequently borne children is probably true, but, at the bedside, neither previous sterility nor fecundity should be allowed to enter as a factor in the diagnosis. It should be remembered that all women during the child-bearing period are liable to the occurrence of extra-uterine pregnancy. If this is borne in mind fewer blunders in diagnosis will occur; and fewer lives will be sacrificed by that criminal procrastination which defers until too late the only rational means of saving the patient's life.

In a typical case the history of the patient is about as follows: There has been cessation of the menses for one, two, or three months, during which time the patient may or may not have experienced some of the symptoms which are supposed by her to be indicative of the occurrence of pregnancy, *viz.*, such as morning sickness, tingling sensations in the breasts, etc. After a time, varying in different cases, she begins to experience colicky pains in the lower part of the abdomen, accompanied by a discharge of more or less blood from the vagina. The blood is sometimes fluid, sometimes clotted, and occasionally shreddy substances are noticed in the discharge by the patient or by those in attendance. Mixed with the vaginal discharge a membranous mass, resembling a cast of the uterine cavity, is occasionally expelled. These symptoms (loss of blood and colicky pains) may disappear to again recur at intervals of a few days, or the flow of blood may be almost continuous and the colicky pains rarely absent for more than a few hours at a time, although they may not be sufficiently severe to confine the patient to bed, or require the administration of anodynes. The flow of blood is rarely profuse, almost never resembling the active bleeding accompanying an early abortion. The typical symptoms, then, are amenorrhea, followed by irregular discharge of blood from the vagina, recurrent colicky pains in the lower part of the abdomen, and occasionally the discharge of portions of deciduous membrane.

Upon physical examination, the uterus will generally be found enlarged if gestation has continued beyond the second month. The softness of the cervix, which is so marked, as a rule, in normal pregnancy, is not always present in ectopic gestation. I have observed it in three cases. In multiparæ the os is sometimes patulous. On one side of, and sometimes behind the uterus, a soft, resilient mass, varying in size according to the stage of the pregnancy, can usually be detected. On careful bimanual examination, it is found to be very close to the body of the uterus, and seems to crowd the organ somewhat to the opposite side of the pelvis. It is, as a rule, not difficult to make out that it is not continuous with the body of the uterus. Examination, *per rectum*, sometimes unables the practitioner to correctly appreciate the relations of the tumor.

The changes in the breasts, characteristic of pregnancy, may or may not be present. In a case presenting the history and physical signs detailed above, there should not be much hesitation on the part of the practitioner in coming to a conclusion in regard to the presence of ectopic pregnancy. If, however, he remains in doubt, an anesthetic should be administered and another careful examination made. Emptying of the bladder and rectum should precede this examination; as, indeed, it should all examinations of the female pelvic organs.

Differential Diagnosis.—The following hints may aid in the differential diagnosis between early ectopic pregnancy and the conditions for which it is likely to be mistaken. In retroflexion and lateroflexion of the gravid uterus, the tumor behind or to one side of the cervix is continuous with it. The cervix is enlarged and softened, and the fundus not in its normal position behind the pubes. There is no colicky pain, and no bloody vaginal discharge—unless an abortion is impending, or has recently occurred. In hydrosalpinx, pyosalpinx, ovarian abscess, small adherent ovarian cyst, and small cysts of the broad ligament, the uterus is not enlarged, and the usual signs and symptoms of pregnancy are absent unless a normal pregnancy coexists. Recurrent colicky pains and irregular bloody discharges from the vagina are not usual accompaniments of these conditions.

In acute pyosalpinx and ovarian abscess, more or less constant pain and tenderness on pressure are present, accompanied by elevation of temperature. In small myomata, the body of the uterus is enlarged, but the menstrual flow is not suppressed, and there is no semi-fluctuating or boggy mass on either side of the uterus.

Early pregnancy in the rudimentary horn of a malformed uterus, cannot be differentiated from ectopic pregnancy; nor is it essential that it should be, as the treatment is operative in both. Pregnancy in

one horn of a well-formed bicornuate uterus may be distinguished from ectopic pregnancy only in cases in which a vaginal or cervical septum exists. In the absence of this distinguishing feature the diagnosis must remain doubtful. From pregnancy in one-half of a double uterus, the differential diagnosis may be easily made, if, in addition to a well-formed double uterus, there is a double vagina. In a case which I saw with my colleague, Dr. Harris, this condition obtained. The patient had symptoms which made the physician apprehensive of the existence of ectopic pregnancy, but after a careful examination it was concluded that the pregnancy had occurred in the right half of the uterus. Both cervices were well developed; and the os uteri of each was normal in appearance. Our determination to wait was rewarded in a few days by a verification of the diagnosis; for the patient aborted.

In a case in which, after careful bimanual examination, serious doubt exists as to whether the pregnancy is intra- or extra-uterine, the use of the sound has been recommended in order to ascertain whether or not the uterus is empty. While the use of the sound may be justifiable in certain cases, its indiscriminate employment cannot be too strongly deprecated.

There are two other conditions which, according to some authors, may be confounded with early ectopic pregnancy, *viz.*, hematoma of the broad ligament, and hematosalpinx. The writer has not referred to these conditions, for the reason that he believes that Bland Sutton is right when he says that nearly all cases of hematosalpinx are the result of a blighted tubal pregnancy, and as regards hematoma of the broad ligament, it is the writer's belief that in ninety per cent. of the cases this condition is the result of rupture of an early tubal pregnancy into the cellular tissue between the layers of the broad ligament.

The diagnosis after rupture of the gestation-sac is based upon the evidences of abdominal shock and concealed hemorrhage. Violent pain in the lower part of the abdomen, followed by symptoms of collapse, is the rule in all cases of intraperitoneal rupture attended by profuse hemorrhage. When the hemorrhage is less profuse the symptoms of collapse come on more slowly. Cases in which the Fallopian tube, the seat of the ectopic gestation, is perfectly free in the pelvic cavity previous to rupture, are, as a rule, attended by more profuse hemorrhage than those in which the tube is bound to surrounding structures by adhesions. The hemorrhage is generally out of proportion to the development of the gestation-sac; the earlier the rupture occurs the more rapidly fatal the hemorrhage.

The two following cases will illustrate these points:

Case III.—I was called by Dr. Flitcroft, May 3, 1894, at 11 A.M., to see Mrs. V., a German, aged twenty-eight years. The patient had never been pregnant before, although she had been married eight years. Her last menstruation had occurred three months previously. When she was first seen by Dr. Flitcroft, a few hours before my visit, she complained of severe pain in the lower part of the abdomen, and there was a slight bloody discharge from the vagina. The doctor made a vaginal examination, and, finding no dilatation of the os uteri, concluded that the case was merely one of threatened abortion. After having given directions as regards the management of the patient, and requested the attendants to send for him should she become worse, he left the house. When he was called the second time he found the patient still complaining of pain in the abdomen, though it was not as severe as it had been at the beginning of the attack. Her countenance, however, had changed, and her pulse was more frequent and weaker than it had been at his first visit. The os uteri was not dilated. The doctor concluded that there was something seriously wrong with the patient, and requested me to see her with him. I found her with a pulse of 126, skin cool, face pale, but not anxious.

She was a short, fat woman; and, on inquiry, I learned that previous to the attack she had had a very florid complexion. The results of a vaginal examination were negative. No swelling of any kind could be detected on either side, or posterior to the uterus.

I expressed to Dr. Flitcroft the opinion that the case was one of ruptured tubal pregnancy, and that an operation should be performed without delay. He heartily concurred in this opinion, and expressed surprise that he should not have made the diagnosis himself in view of his previous experience.[1]

As the environments of the patient were such as to preclude the possibility of operating upon her in her own home, she was removed as quickly as possible to the Paterson General Hospital. As showing how very important it is not to waste any time in this class of cases, I will state that in the time which it took to remove the patient to the hospital the change for the worse in her condition was really alarming. Her pulse rose to 156, and the surface was cold and covered with perspiration. She appeared to be moribund, and yet the time occupied in her removal was less than two hours. Hot saline solution and brandy was injected into the rectum, the field of operation quickly prepared, and the patient anesthetized and taken to the operating-room. Assisted by Dr. Jas. W. Smith, I performed abdominal section.

As soon as the peritoneum was incised fluid blood

[1] Dr. Flitcroft had had within two years the unique experience of being present at the bedside of a patient at the moment of rupture of a tubal pregnancy. The patient was conversing cheerfully with the doctor when she was suddenly seized with an agonizing pain in the abdomen, and very soon afterward showed symptoms of collapse. Dr. Flitcroft called to his aid Dr. C. S. Van Riper, who promptly opened the abdomen and removed the ruptured gestation-sac. A large amount of blood was found in the peritoneal cavity. The patient recovered.

welled up from the abdominal cavity and ran down upon the floor of the operating-room. I quickly passed my fingers down through the mass of blood-clot into the pelvic cavity, and found that the ruptured gestation-sac was the left Fallopian tube. This was brought up into view through the incision, when it was observed that there was a rent in its walls through which the fetus had escaped, and from which bright-red blood poured in a constant stream. A figure-of-eight ligature was applied and the sac cut away. The abdominal and pelvic cavities were cleansed of blood, flushed with hot saline solution, and the abdominal wound closed. A three-months' fetus was found among the blood-clots; the placenta had been retained within the sac and was removed with it. It was estimated that more than a gallon of blood had been removed from the peritoneal cavity. Although the patient's condition was desperate at the time of operation, she rallied under the influence of active stimulation, and made an excellent recovery.

Case IV.—Mrs. R., aged twenty-three years, married nine months, was admitted to the Paterson General Hospital, January 21, 1897. The history was that she had been seized with violent pain in the abdomen the evening previous to admission, and had gradually gone into the condition of collapse in which she reached the hospital. Shortly after she was taken ill she was seen by Dr. John T. Gillson, but when the doctor was informed by the patient that she had menstruated regularly—the last time only three weeks previously—he dismissed the idea of ectopic pregnancy from his mind, and attributed the pain to some form of intestinal disturbance. When he saw her the following morning he became convinced that intraperitoneal hemorrhage was going on, and sent her to the hospital. I was at the hospital when she was admitted, and the senior house-surgeon requested me to see her at once. She was almost pulseless, and death seemed imminent. The extreme pallor of the surface and waxy appearance of the lips, taken in connection with the sudden onset of the attack, in a person previously in robust health, left no doubt in my mind as to the existence of intra-abdominal hemorrhage. The result of a vaginal examination was entirely negative—nothing abnormal could be detected.

The rectum being found empty, a stimulating enema of hot saline solution and brandy was at once administered, and the field of operation having been prepared, abdominal section was performed. On opening the peritoneal cavity a large quantity of fluid blood escaped. The whole abdominal and pelvic cavities were filled with clotted blood. The right Fallopian tube was the source of the hemorrhage and was removed, together with the ovary, which was cystic. The ectopic sac was situated almost at the fimbriated end of the tube, and was lined by a rather thick membrane. Its size, when collapsed, would indicate that before rupture it was no larger than a hazelnut. In spite of active stimulation, the patient never rallied and died within twenty-four hours.

In this case the exsanguination was complete, and no amount of saline solution could take the place of the blood lost. Had this patient been operated upon early there is every reason to believe that she would have recovered. Her history, however, was misleading, and her physician was at first deceived by it. In this and the preceding case the fetal sac was entirely free from adhesions to surrounding parts.

When rupture occurs between the layers of the broad ligament the evidences of shock and loss of blood may be marked, but rarely to the same extent as when it occurs into the peritoneal cavity. The differential diagnosis rests upon the result of a physical examination. A large, soft, boggy mass is found on one side, and posterior to the uterus. The uterus is crowded to the opposite side, and the cervix is pushed under the pubes, and, in a large proportion of cases, the os uteri seems to point directly upward. I know of no other condition which gives rise to this particular form of uterine displacement. I regard it as a sign of the greatest diagnostic value. If a physician previously makes a vaginal examination and detects a small mass on one side of the uterus, its sudden increase in size, accompanied by symptoms of shock and concealed bleeding, can be due but to one cause, *viz.*, intraligamentous rupture, with hemorrhage between the layers of the broad ligament. When rupture of an early tubal pregnancy into the peritoneal cavity occurs, any small mass, situated on one side of the uterus, which may have been previously detected, will generally be found to have disappeared, unless the pregnant tube is bound down by adhesions, and the effused blood, to a certain extent, encapsulated. The treatment of extra-uterine pregnancy should be purely surgical, all other methods should be condemned as both inefficient and dangerous. If the diagnosis is made before rupture has occurred, the abdomen should be opened and the gestation sac removed. If rupture has already occurred, not a moment should be lost in resorting to abdominal section, for a very brief delay may result in the death of the patient from hemorrhage. When the abdomen is opened there is generally an escape of fluid blood and the pelvis is found filled with blood-clots, through which the surgeon passes his fingers to the fundus of the uterus, and then along the broad ligament on each side until the site of the gestation-sac is determined. The sac is immediately brought to the surface, securely ligated at its base, and cut away. The abdominal and pelvic cavities are then flushed with hot saline solution, and sponged until free of blood. If the sac is found adherent to surrounding structures the use of a drainage-tube will add to the patient's changes of recovery. If the hemorrhage has been great, and the patient is much

depressed, hot saline solution should be injected into the rectum. Brandy or good whisky may be given with the saline solution, and may also be given by the mouth in small doses frequently repeated, and in very hot water, as hot as the patient can bear. Morphin and strychnin administered hypodermically are generally indicated. When the patient has reacted her strength should be supported by nutritious liquid diet.

Intraligamentous Rupture.—When rupture of an early tubal pregnancy occurs and the fetus (fetal débris) and effused blood escape between the layers of the broad ligament, constituting what was formerly known as extraperitoneal hematocele, but now designated hematoma of the broad ligament, the interests of the patient will be best secured by letting her alone. These cases, as a rule, are fatal only through the officiousness of the medical attendant. If the patient be kept quiet, and trust put in *meditrix naturæ*, it will generally be found that at the end of a few weeks the effused blood and fetal remains have been absorbed, and that nothing is left but a slight thickening of the broad ligament on the affected side.

The only exception to this rule occurs in cases in which suppuration of the hematoma supervenes, or in those very exceptional instances in which, after primary intraligamentous rupture, secondary rupture through the roof of the broad ligament into the peritoneal cavity occurs. Cases of the latter class demand prompt and decisive action. The abdomen must be opened, the cavity of the broad ligament emptied of clots and packed with iodoform gauze, an end of which should be brought out through an opening in the vagina for drainage. The rent in the roof of the broad ligament may then be closed with a fine catgut suture. If the hemorrhage cannot be controlled in this manner, hysterectomy should be performed. In suppurating hematoma of the broad ligament, vaginal section, washing of the cavity with a disinfectant solution, and gauze drainage are indicated. It will be observed that in the treatment of ectopic pregnancy in the early months, abdominal section is the only method which I have advised. My reasons for so doing are, in the first place, my personal experience is limited entirely to this operation, and, in the second, I fail to appreciate the advantages of operation by the vaginal route which are claimed by the advocates of that method. The operation through the abdominal wall gives more room for work; the manipulations are performed under the guidance of the sense of sight, as well as touch, and in cases of intraperitoneal rupture, with the accumulation of large quantities of clotted blood in the abdominal and pelvic cavities, the cleansing of the peritoneal cavity can be more quickly and effectually performed.

Summary.—The points which I wish to emphasize are as follows:

1. Early ectopic pregnancy may be diagnosed before rupture has occurred, provided an opportunity to make a careful examination be afforded.

2. In the differentiation of early ectopic pregnancy from conditions which simulate it, a painstaking examination *per vaginam* and *per rectum*, under anesthesia, offers the best chance of making a correct diagnosis.

3. The use of the uterine sound as a means of diagnosis may be permissible in cases of grave doubt as to whether the pregnancy is intra- or extra-uterine; but its indiscriminate employment cannot be too strongly condemned.

4. In case of grave doubt as to whether or not early ectopic pregnancy be present, but when the presumption is strongly in favor of its existence, exploratory abdominal section is not only permissible, but imperative.

5. Abdominal possesses many advantages over vaginal section, and should, therefore, always be the operation of election in this class of cases.

6. All cases of early ectopic pregnancy, except those in which intraligamentous rupture has occurred, should be operated upon as soon as the diagnosis is made. Procrastination may mean death to the patient.

VIBRATORY THERAPEUTICS.

BY FREDERICK PETERSON, M.D.,
OF NEW YORK;
PROFESSOR OF INSANITY IN THE WOMAN'S MEDICAL COLLEGE;
VISITING NEUROLOGIST TO THE CITY HOSPITAL.

IN view of the well-deserved attention during recent years to the various so-called natural methods of treating disease, such as massage exercises, hydrotherapy, dietetics, and the like, I have thought it well to add my experience to that of several others in regard to the rather novel method of treatment of nervous diseases by means of vibration. Vibration may properly be divided into two classes, *viz.*, mechanical and kinetic. The former is obtained by means of a variety of vibrating mechanical apparatus. The term kinetic seems to me applicable to the finer variety of vibration induced by some force such as electricity, an example of which is afforded by the sinusoidal current.

Mechanical vibration for therapeutic purposes was in use long before any mention of it found place in medical literature; for its value was recognized by the earliest of the originators of the Swedish system of gymnastics and massage. It was practised before Zander devised mechanical apparatus for the pur-

pose. It seems to have been as late as 1878 before it attracted the attention of physicians and was made the object of investigation both as to therapeutic value and mode of action. Thus, in the same year appeared Horvath's[1] article on "The Influence of Rest and Movement upon Life," and the article by Vigouroux[2] upon "The Results of Vibratory Treatment of Nervous Diseases in the Service of Charcot at the Salpétrière." The next reference to the subject was made two years later by Mortimer Granville, who applied vibration to the treatment of neuralgia, and he invented a vibrating hammer for application of vibration to affected nerve trunks. He published brief articles during 1880 and 1881 in the *Lancet*, and, during 1882 and 1883, in the *British Medical Journal*, but his brochure, entitled "Nerve Vibration and Excitation as Agents in the Treatment of Functional Disorders and Organic Disease," was not published until 1883. Baudet published an article on the treatment of pain by mechanical vibration in *Progrès Médical*, February 5, 1881. With the exception of an occasional biologic reference to the subject, such as Reinke's article in *Pflüger's Archiv*, 1880, on the influence of mechanical shaking on the development of certain fungi, and one or two others mentioned by Meltzer in his paper on "The Importance of Vibration to Cell-life" (*New York Medical Journal*, December 24, 1892), nothing appeared in medical literature in relation to vibration until Charcot (*Prog. Méd.*, p. 149, 1892) and Gilles de la Tourette (*N. iconog. de la Salpét.*, p. 265, 1892) introduced the matter again to the profession with considerable acclaim. Outside of strictly medical circles, however, vibratory therapeutics had continued to develop, and before Charcot's paper was published the vibrating machine invented in Sweden by Liedbeck had been in use and even covered by an American patent as early as 1890.

W. B. Tomson published a brief note in the *Lancet*, i, p. 1299, 1890, entitled "General Appreciation of Vibration as a Sense Extraordinary," citing the cases of two deaf persons with remarkable sensitiveness to vibration; an interesting note from a speculative point of view, because the nervous system does seem to be often susceptible in an extraordinary degree to mechanical vibration. Morselli, during 1892 and 1893, wrote upon mechanical vibration as a means of cure of nervous and mental diseases, and his work is especially interesting and valuable (*Terap. Mod. Padova*, 1892, vi, 568, and also *Boll. d. r. Accad. med. di Genova*, 1893, 33).

With the exception of a paper by Dr. Patrick in the *Chicago Medical Recorder* during 1894, the above constitutes all I have been able to find in medical literature on vibratory therapeutics.

Regarding the apparatus used for the purpose, Larat and Gautier made for Charcot and Gilles de la Tourette the *casque vibrant* and the *fauteuil trepidant* employed by them. The *casque vibrant* is simply a metal helmet upon the top of which is fixed a small electric motor, its trembling motion being communicated by this means to the whole head. The *fauteuil trepidant* or shaking chair was constructed especially for cases of paralysis agitans, but is also used for other purposes, and is merely a chair mechanically adjusted to simulate the tremor of a train or omnibus.

In my own practice I have employed three varieties of apparatus. The first is a modification of the one in use at the Salpétrière. It was made for me by Messrs. Waite & Bartlett of New York, and consists of a small motor with an eccentric adjustment to regulate the force and frequency of the tremor. This motor is fixed upon the head by means of clasps and a strap (Fig. 1).

Fig. 1.

Electric vibrator for the head.

Another instrument made for me by the same firm is modeled upon the electric engraving-tool. It consists of a rod with an up and down movement affixed to the same motor used for vibrating the head. With this apparatus the trunks of nerves may be tapped and vibrated with any degree of frequency required (Fig. 2).

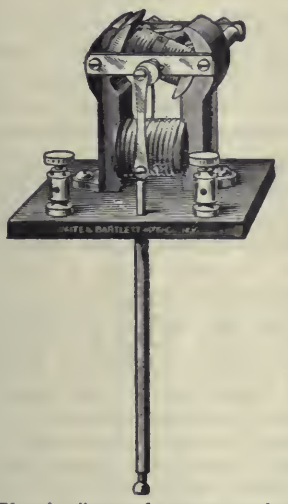
The third and best apparatus is one which may be used for administering vibration to any part of the body, to a nerve trunk, to the eye, the larynx, the head, a limb, the spinal column, and with any degree of force or frequency desired. It is an adaption

[1] *Pflüger's Arch.*, 1878, p. 125.
[2] *Prog. Méd.*, 1878, p. 746.

of the Swedish Liedbeck machine, but is operated by electricity (Fig. 3).

The effects of vibration will vary with the degree

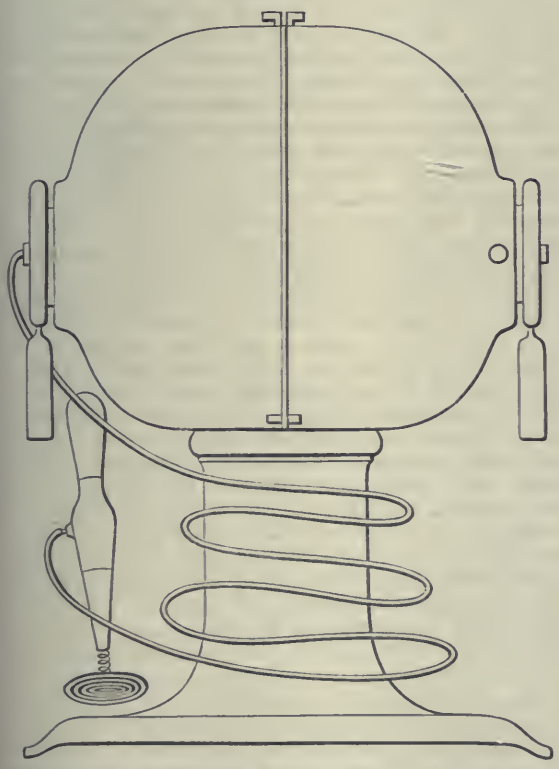
FIG. 2.



Electric vibrator for nerve trunks.

and duration of the application. A harmful effect may be induced by too prolonged vibration, while

FIG. 3.



Leidbeck's electric vibrator for general use. It is provided with a number of terminals suitable for application to any part of the body.

moderate vibration has a favorable action, as shown by Meltzer in his experiments on the influence of shaking upon micro-organisms. Prolonged shaking destroyed the germs. Meltzer assumes, and rightly it appears to me, that shaking produces a vibration in the physiologic units of cells. It may be considered an established fact that one of the direct effects of vibration is to modify nutrition in the part treated. Growth is stimulated by mild vibration; strong vibration causes rapid katabolism. The chief virtue of this form of therapeusis lies in its influence upon the nervous system. Applied to the head, the whole skull-wall is shaken, together with the brain, and in a few minutes a pleasant torpor or lassitude is experienced with a tendency to sleep. A ten-minutes' séance will often induce a sound night's sleep in insomnia, and the Charcot school has claimed that eight to ten such séances completely cure insomnia when it is not due to organic brain disease. During the séance a dim monotonous murmur is heard in the ears. On cessation of the tremor sometimes a light vertigo is experienced. Applied to the spine or to large nerve trunks, a similar restful feeling is induced with an inclination to drowsiness. In fact, the effect upon the nervous system is that of a powerful sedative. This is borne out by its use in paralysis agitans, and I can corroborate the statements of the Charcot school that it causes the tremor to diminish, lessens the rigidity, and above all causes the disappearance of one of the nearly insupportable symptoms of Parkinson's disease, the general feeling of restlessness, malaise, and fatigue. I have tried it in some of the neuralgias of peripheral nerves, in neurasthenic and hysteric conditions and in headaches, I have also made use of vibration in hysteric aphonia and in obstinate ringing in the ears. In all of these conditions its therapeutic effects were marked and valuable.

CLINICAL MEMORANDUM.

A PERSONAL EXPERIENCE IN RENAL SURGERY.

BY ROBERT F. WEIR, M.D.,
OF NEW YORK;
PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, AND SURGEON TO THE NEW YORK HOSPITAL;
WITH THE COLLABORATION OF
EDWARD M. FOOTE, M.D.,
OF NEW YORK;
SURGEON TO THE RANDALL'S ISLAND HOSPITALS.

(Continued from page 111.)

ABSCESS OF THE KIDNEY.

IN this group of cases are found two of traumatic origin, both of which were treated by means of nephrotomy. The result in one case, a recent one, was perfect. The other patient died within four days of suppression of the urine, and it was found that of the injured kidney only a fragment remained, and that the other one was

affected by a diffuse suppurative inflammation. Following these instances, are two of idiopathic abscess, in one of which, originating in a gonorrhea, coli bacillus was extensively found in the minute multiple abscesses of the extirpated organ. Both patients did well after nephrectomy.

Surgical aid has not, I believe, until recently been extended to that form of renal sepsis which is mentioned under the title of "surgical kidney," or suppurative interstitial nephritis. By this is meant the acute infection which often occurs in this viscus from a rapidly ascending inflammation, and which shows itself at the autopsy, for it is always fatal in its results, as a swollen and congested kidney studded with numerous pus foci. The smallest of these are not visible to the eye, but microscopically groups of pus-cells are found between the tubules. Larger purulent streaks surrounded by zones of congestion are also often seen running parallel to the tubules. Great numbers of miliary abscesses may be seen or felt on palpation. In the living kidney it is sometimes difficult to recognize the small purulent collections because of the bleeding of the incised kidney, though their touch often aids the ineffectual vision. Therefore, from its great interest, I venture to report, in a condensed form, the following history of a case of this kind, previously published,[1] wherein the nephrectomy saved the patient's life. It marked an advance in renal surgery, and has since been followed in several instances by German colleagues.

CASE XIX. *Multiple Septic Abscesses of Kidney (Acute Surgical Kidney)—Nephrectomy—Recovery.*—Henry D., aged twenty-five years, entered New York Hospital, March 28, 1894, with a history of nephritis existing for four years, following scarlet fever. One year before admission he had had gonorrhea, and again three months before he had had a second attack of the same disease, the last invading his bladder. The cystitis improved, but twelve days before entrance to the hospital it grew worse, with the development of chills and fever, nausea and vomiting, and pain in the right lumbar region. On April 3d, when I saw him by request of his medical adviser, Dr. P. R. Bolton, he was in a serious condition, with an irregular temperature ranging from 101° to 105°F., and an acid urine containing pus and about twelve per cent. of albumin by volume. The right kidney was very tender and slightly enlarged.

April 4th, by means of König's curved incision, the kidney was exposed. No pus could be obtained by aspiration, but an incision was made into the organ, which was twice its normal size, deeply congested, and softened. It was then seen to be riddled with minute abscesses, and was removed after ligation of the pedicle and ureter with floss silk. The cavity was packed with gauze, and the wound partially closed. The patient left the operating-room in good condition, but collapsed within two hours. Under vigorous stimulation his condition improved, and he gradually became convalescent. The ligature separated within one month. Six weeks after the operation there was still a small amount of pus in the urine, and about eight or ten per cent. of albumin by volume, but there were no symptoms referable to the bladder. He was discharged in good condition with a superficial granulating wound in his loin. Cultures from the nephritic abscesses developed colonies of the bacillus coli communis, but none of the gonococcus. The kidney measured 14x6.5 x4.5 inches. The patient made a complete recovery, and when heard from, three weeks later, was in good condition.

In this patient, the mass of symptoms being confined to one side, led me to believe that the infection was limited to this kidney alone. This determined the extirpation. As to the frequency one may expect to find an infection of this character similarly located, the investigation I made of the material of New York and St. Luke's hospitals showed that in forty-five cases of true surgical kidney (large single or multiple abscesses and those of chronic form being excluded), in six instances it presented itself as a one-sided lesion. Malherbe and Bazy also found twenty-six cases of this disease in which six were one-sided. In other words, in about seventeen per cent. of all the cases the affection is confined to one kidney. Even if both sides are affected a double incision might give the otherwise doomed patient a chance.

CASE XX. *Laceration of the Kidney—Pyelonephritis—Nephrotomy—Recovery.*—Mary O., aged twenty-six years, married, was admitted to New York Hospital, October 6, 1884. During the previous May she had had a miscarriage, with persistent uterine hemorrhages and attacks of abdominal inflammation. Her symptoms had disappeared by August 15th. One month later, just after a menstrual period, she again began to have pain in the abdomen, with nausea and fever. Urination was frequent and painful, and the urine contained pus, casts, and blood. The patient denied having received any injury. A needle thrust into a swelling in the right iliac region drew pus. The nature of the swelling, which extended from the liver almost to the ilium and was nearly five inches broad, was in doubt. A second and third punctures, made on different days, produced only blood.

Meanwhile her condition was comfortable and the urine nearly normal, though the temperature continued to reach 105° F. each day. On the fifth day after entrance pus was again obtained, and the patient was etherized for operation. Her physician, who was present to witness the operation, then furnished the important information that ten days before coming to the hospital Mrs. P. was kicked in the side by a person whom she was unwilling to implicate, and that for two days she passed bloody urine. In the hope that the abscess might be perinephritic an incision was made over the outer border of the tumor. This proved to be an unfavorable point of attack, and after the peritoneum had been opened and the inflamed kidney palpated the wound was closed and an incision made along the edge of the quadratus lumborum muscle. There was no perinephritic deposit of pus, but the kidney, when exposed, was found so softened by suppuration that the finger could easily be poked through it in one place into a gangrenous cavity, while a jagged rent ran from this downward along the border of the organ, evidently a laceration from the kick she had received. The cavity was drained, and within one month the wound was entirely healed. The tumor rapidly diminished from the time of operation, but two months afterward there was still some hardness at the region of its lower portion, due presumably to post-operative perinephritic inflammation.

CASE XXI. *Laceration of the Kidney—Perinephritic Abscess and Renal Fistula—Nephrotomy and Subsequent Nephrectomy—Death.*—Bernard M., aged twenty years, entered New York Hospital during the fall of 1886. Three years previously he had fallen six feet and struck his right side upon an iron bar. Hematuria, followed by local pain, swelling, and fever showed an in-

[1] Weir, *Trans. Am. Surg. Ass.*, vol. 12, p. 121, 1894.

jury to the kidney, resulting in an abscess. An incision was made into this by my colleague, Dr. Bull, and a large amount of pus evacuated. The resulting sinus healed, but subsequently opened several times. Since July, 1886, the pain in the flank and in the rectum prevented the patient from going about. Examination showed a large fistulous opening in the right loin midway between the ribs and ilium. From this, a probe passed nine inches downward into the iliac fossa along a tract which was both indurated and tender. Near this fistula was another leading toward the kidney to a depth of four inches. These openings discharged from four to six ounces of pus daily. Rectal examination was negative. The urine was slightly albuminous, and contained a few pus-cells. The daily excretion was from fifty to sixty ounces. The patient's condition was poor. He was steadily deteriorating in general health.

Under ether, a curved incision passing through both fistulæ was made through tissues matted together by old inflammation, and a cavity was opened through the thin wall of which the movements of the abdominal viscera were plainly felt. The sinus into the iliac fossa was then laid open, and another one extending into the pelvis was also drained. Examination of the cavity with an electric lamp showed a rent in its wall three inches long through which the liver and gall-bladder were visible. As no kidney had as yet been found, search was made for it through this opening into the peritoneal cavity, but no trace of it was discovered. The rent was closed with catgut sutures, and the wounds filled with gauze. Death occurred four days later. There was a marked rise of temperature forty-eight hours after the operation, followed by persistent vomiting and almost complete suppression of urine.

At the autopsy, the left kidney was found in a state of acute suppurative interstitial inflammation with pus under its capsule. There was no peritonitis. The lower two-thirds of the right kidney had entirely disappeared. The upper portion of the cavity referred to was formed by what was left of the kidney. In this cavity were two sponges, which had been crowded in to control hemorrhage, and had been left *in situ*. One of them was firmly adherent. They had not given any foul odor to the discharge. The sinus leading into the pelvis terminated behind in a pus-cavity, which led to the bladder and rectum and also extended through the right sacrosciatic notch, outside of which pus had collected to the amount of nearly two ounces.[1]

CASE XXII. *Pyonephrosis — Nephrotomy — Recovery.*—Emma T., aged forty years, suffered some months from indefinite dragging pains, followed by a sudden attack of severe lumbar pain in the right side. After this attack a tumor was for the first time observed, and the patient entered the hospital. In the right lower quadrant of the abdominal cavity could be detected a tumor the size of a child's head, not moving on respiration, and nearer than usual to the median line. The urine was of neutral reaction, had a mucus sediment, a specific gravity of 1014, and contained a trace of albumin. There were a few leucocytes and epithelial cells in the sediment. Owing to some doubt as to the origin of the tumor, on October 4, 1896, a small exploratory incision was made and showed it to be a greatly dilated kidney. The abdominal wound was closed, and the usual curved incision made in the loin. The sides of the wound were smeared with Whitehead's solution of tincture of benzoin and iodoform, and the kidney incised. About three pints of pus escaped. A probe was passed eighteen inches down the ureter, but it could not be detected in the bladder. There was no evidence of stone. The kidney was drained by means of iodoform gauze and two rubber tubes, and the wound partially sutured.

Recovery from the operation ensued. The wound discharged much pus and was dressed daily. Within fifteen days one tube was removed, and the other within about four weeks. Within eight weeks the lumbar wound had entirely healed, and the patient went home. For a time after the operation the urine was free from pus and albumin; but within a month, when the discharge from the loin had greatly diminished, there was a daily passage of forty-two to fifty-two ounces of urine containing a trace of albumin and having a mucopurulent sediment of from one to two ounces. In December, 1897, the patient was in excellent health, suffering no pain on the affected side, and urinating clear urine four or five times daily. There was no enlargement of the kidney to be felt, and no weakness of the cicatrix.

HYDRONEPHROSIS.

In the days of the Lister spray, now nearly forgotten, though less than twenty years have passed, a patient (Case XXIII.) came to me complaining of a lumbar swelling which proved, upon aspiration, to be a hydronephrosis. This puncture was followed by an incision and drainage, and after several superficial abscesses had been opened in the cicatrix the patient recovered. The case has been already reported,[1] but it is here again epitomized, not only for the sake of completing the record, but also for its historic interest, since, somewhat to my surprise, it has been recorded by Brodeur[2] as the first operation ever resorted to for a hydronephrosis. Two other cases, in each of which the tumor was of large size, are also in our list, one of which was before the date of Fenger's suggestion to save the kidney, if possible, by anastomosing the ureter below the stenosis to the renal pelvis above. The second one, however, in my judgment, promised so little, that extirpation was resorted to. Indeed, I do not think when such a thinned and interstitially changed renal substance is met with, as in a large hydronephrosis, any benefit can be obtained by conservative means. With hydronephrosis confined to the pelvis or only moderately involving the kidney tissue anastomotic procedures come properly into use.

CASE XXIII. *Hydronephrosis — Nephrotomy—Recovery.*—John W., aged twenty-one years. Soon after an attack of vague abdominal pain he noticed a slight swelling in the left iliac region, and when he entered New York Hospital, November 1, 1878, the tumefaction extended well up the side and downward to the ilium. Two ounces of limpid fluid, of a specific gravity of 1012, was withdrawn. No urea nor echinococcic hooklets were found in it. A second tapping, withdrawing twelve ounces of fluid, resulted in similar findings.

As the tumor increased to a considerable size, an

[1] There has been omitted from the above list of kidney lacerations one which occurred in a girl aged eleven years, who fell twenty feet, striking the left side on a bar. Laparotomy was resorted to twenty hours later, as her general condition warranted interference for the supposed displaced intestine. Much blood was found in the peritoneal cavity, and the kidney was found to be dislocated downward with its hilus and ureter torn across, the artery remaining intact, forming a huge hematoma. This organ was removed, but the bleeding still continued. A further search revealed that the blood came from a badly torn spleen. The damage necessitated the removal of this gland. Temporary improvement with death at the end of nine hours was the result.

[1] Weir, *Med. Record*, March 13, 1880.

[2] Brodeur, "De l'Intervention Chirurgicale Dans Les Affections Du Rein, 1886."

incision was made, December 20, 1878, in the loin, as for lumbar colotomy, and a dilated kidney exposed. This was punctured to the depth of one-quarter of an inch, and two pints of a semi-transparent fluid freely escaped. A drainage-tube was inserted, the outer end of which communicated with a rubber bag filled with carbolized sponges, covered with carbolized jute. The operation was made under carbolic spray. The following day the ureter was explored by my flexible metallic probe, used then for the first time, to a depth of nine inches from the surface wound, but no calculus was found. During April, 1879, the drainage-tube was removed, and the wound was allowed to close. Four times an abscess formed in the scar, and was lanced. After that recovery was complete. There were no symptoms referable to the urinary tract, and no tumor could be felt. All attempts to learn the subsequent history of this patient have failed.

CASE XXIV. *Hydronephrosis — Nephrectomy—Recovery.*—Joseph G., aged fifteen years, presented the following history: For a long time he had noticed that his abdomen was growing larger, particularly on the right side, but there was no pain, and no urinary symptoms. There had been increasing loss of flesh and strength, but no history of colic or ureteral obstruction. March 7, 1891, two months before his entrance to New York Hospital, the greatly dilated hydronephrotic sac had been incised in the lumbar region by my colleague, Dr. W. T. Bull, and several pints of a clear fluid evacuated. The urine before the nephrotomy had been pale, alkalin, of a specific gravity of 1013, and with a faint trace of albumin, but no sediment. The hydronephrotic fluid was of a specific gravity of 1009, and contained about one-half the amount of urea contained in normal urine.

The sinus persisted, discharging freely, and led to a cavity capable of holding 1½ pints of fluid, and on May 9, 1891, the sinus was enlarged above and below to a width of four-fifths of an inch, and its cavity exposed. It was found to consist of a thin-walled sac, with occasional traces of kidney tissue, reaching from the iliac fossa to the diaphragm. It was dissected out, its vessels and ureter, the last being an obliterated cord for more than two inches, separately tied, and the organ removed. The patient made a good recovery. At first, the quantity of urine voided from the bladder was below the normal, as it had been before this second operation, but soon it increased in amount from thirty-six to forty-five ounces daily. It contained a few casts for some days.

The patient gained flesh and strength, and left the hospital three weeks after the nephrectomy in good condition with the wound completely closed. He was seen during December, 1897, in good health. The scar was double, the straight one being along the quadratus lumborum muscle, and the oblique one parallel to the twelfth rib and about five inches long. Between the anterior end of this and the rib, on coughing and expulsive effort, a decided hernial bulging could be observed. However, no muscular weakness could be felt on that side.

CASE XXV. *Hydronephrosis — Nephrectomy—Recovery.*—Miss B., aged twenty-two years, a patient of Dr. A. Cushier, noticed, four years before operation, a swelling in the right lumbar region. This increased with, and was accompanied by, a dragging sensation in the back, and occasional attacks of sharp pain, but no urinary symptoms. Upon entrance to the hospital, the temperature was 99.8° F.; respiration, 22, and pulse, 80. The urine had a specific gravity of 1023. It was acid, without albumin or sugar, and its sediment presented nothing abnormal. The swelling in the lumbar region was the size of a cocoanut.

October 19, 1896, the tumor was exposed by a crescentic incision. It proved to be a large hydronephrotic cyst of the kidney. With a trocar and canula about twenty ounces of clear urinous fluid was withdrawn, and the cyst was opened. A long flexible probe inserted into the ureter, down to brim of the pelvis, detected no stricture, nor was the cause of the hydronephrosis discovered. Some difficulty was encountered in passing the probe, but much help was given by turning the dilated kidney inside out until the pelvis was recognized. As the kidney substance was generally reduced to an extreme thinness, and as it was much degenerated, it was determined to extirpate the organ. It was readily detached from its bed, and after the vessels and ureter were ligated, it was removed. As is my late custom after a nephrectomy, the cavity of the wound was lined with a Mikulicz "bag," or layer of iodoform gauze, six-tenths per cent., and inside of this was packed quite forcibly sundry handkerchiefs of sterile gauze, the ends of which emerged from the unsewed portion of the wound. This controls admirably any oozing, and the interior packing is removed at the end of one or two days, and the iodoform gauze a little later. The patient made a good recovery, except for a moderate sero-hemorrhagic discharge into the dressings, which occurred within the first twenty-four hours and persisted as a bloody grumous discharge for ten days. There was at first a very small amount of urine passed, but this reached thirty-eight ounces on the third day, and was nearly normal in character, having only a slight trace of albumin, which later disappeared.

The examination of the excised kidney showed it to be greatly distended and hydronephrotic, and to be made up of several cysts. The kidney tissue left was slight in amount and showed to a marked degree, on microscopic examination, chronic inflammatory changes. The ligature remained attached for seven weeks, and was only removed by means of my rubber-ball tractor,[1] which need not be described as it has been superseded by the better methods of Cleveland and Grad, to be referred to later. The patient was heard from fifteen months afterward, and she had gained in strength and was in good condition.

(To be continued.)

THERAPEUTIC NOTES.

Treatment of Metrorrhagia.—CONNERY (*Intercollegiate Med. Jour.*, December, 1897) speaks of the importance of an exact knowledge of the cause of metrorrhagia before treatment is attempted. He calls attention to the fact that cardiac, hepatic, or renal diseases have frequently produced metrorrhagia, although uterine disorder has been absent or slight. In such cases diaphoretic remedies should be given, according to the condition of the patient. Reliable remedies for checking hemorrhage are few. Hydrastis Canadensis is of value in many cases, and is too little known. Quinin and strychnin administered alone or in combination will often arrest hemorrhage in cases associated with debility. Absolute rest in a horizontal position and vaginal douches with the water at a temperature of 110° to 115° F., will often suffice to control hemorrhage. If in spite of treatment the bleeding continues without assignable cause, the cavity of the uterus should be explored; for a bleeding polyp or submucous fibroid has been known to produce death by loss of blood, although in itself it may be a comparatively trivial affair.

SATURDAY, JANUARY 29, 1898.

PHILADELPHIA'S TYPHOID-FEVER EPIDEMIC; WHERE DOES THE RESPONSIBILITY LIE?

PHILADELPHIA, at the present moment, furnishes the unfortunate spectacle of a community of considerably more than one million souls needlessly plunged into a rapidly spreading and thus far unchecked epidemic of enteric fever, and absolutely helpless to rid herself of the pest because of the refusal of her city legislators to cooperate with the health authorities, and to provide a water-supply which may be used with safety. For months, yes, for years, Common and Select Councils, the governing bodies of that city, have been importuned to pass an ordinance for the establishment of a filtration-plant. The long-standing high mortality in Philadelphia from typhoid fever should have resulted years ago in the erection of filtering-stations and adequate storage-basins for the improvement of the water-supply, but the members of Councils, true to their traditions as professional politicians, have steadfastly declined to provide these safeguards to the health of citizens whose interests they are popularly supposed to represent—failed to provide the safeguard simply and solely because they were unable to effect among themselves, in taking such a step, a sufficiently remunerative plan for the division of the spoils attending the undertaking; for is not such remuneration, after all, the actual *raison d'être* of the vast majority of city law-makers of this brand? Thus it is that through the criminal neglect of this group of spoilsmen the present epidemic of enteric fever, for an epidemic it certainly is, has been needlessly inflicted upon our neighbors in Philadelphia, who must suffer physical ills and loss of life, unable to avert the danger by appeals to their representatives in Councils, and chafing under an injustice which carries with it a feeling of personal insult to every self-respecting citizen.

Since the beginning of the present outbreak, the first week of last December, 1134 new cases of enteric fever have been reported in the City of Philadelphia, and of this number 675 have occurred during the first four weeks of the new year, or an average of more than 168 new cases weekly up to the present time. As a striking comparison, we may state that during two weeks of the present month New York City—exclusive of Brooklyn, etc.—with a population twice that of Philadelphia, reported a total of 36 new cases of typhoid, while Philadelphia for the corresponding period, reported no less than 366 new cases! To further the comparison, two wards in the infected district of Philadelphia, having a combined total population of 100,000, in *one* week surpassed the total roll of enteric-fever cases reported among the 2,000,000 inhabitants of New York City for a period of *two* weeks. To make the contrast still plainer, in one recent week in New York City, only six new cases of typhoid were reported from the densely populated tenement districts below Fourteenth street, where the nature of the surroundings and mode of life offer every advantage to the development of filth-diseases. On the other hand, the section of Philadelphia in which typhoid is most prevalent is an area not of crowded tenements and of indifferent hygienic environment, but of separate, small dwellings, occupied, as a rule, each by a single family, and pronounced by the corps of health inspectors, which have just investigated the neighborhood, admirably drained and perfect as to all sanitary appliances.

As to the cause of the epidemic there is no uncertainty. The Schuylkill River, from which the greater

part of Philadelphia's water-supply is derived, is polluted from end to end, and this foul, sewage-laden water is served, unpurified, to the patient taxpayer. Last November an accident occurred by which sewage was pumped directly into a reservoir, and thence into the city water-mains to the consumer; and this accident seems to have been a principal cause of the present outbreak. It is also known that further up the river typhoid is on the increase, and this adds another factor to the cause of the epidemic. But to enumerate these causes is of no avail. The Schuylkill is polluted, and every one has known the fact for years. Every one also knows that the practical remedy for the situation is either through filtration or an entirely new source of the water-supply. The majority of voters expressed in unmistakable terms their approval of filtration by the creation of a loan-bill last fall which empowered the city to borrow a large sum for general municipal improvements, including the sum of $3,700,000 for the immediate improvement and filtration of the water-supply; and yet, in spite of the fact that money is available for the project, that the people urgently favor it, and that the city health-officers heartily endorse the scheme, Councils persist in ignoring the situation, and criminally delay the appropriation of the money at their disposal to provide adequate filtration-plants for the city. Pleas, arguments, and merited censure on the part of the citizens at large, the daily press, and the medical profession, have failed to convince this body of its imperative duty, and the members continue to snap their thumbs at measures of public safety by suggesting that an appeal be made to the Government for aid in dealing with the epidemic, instead of acting without hesitancy in accord with the demands made upon them from every side. They richly deserve for their utter incompetency in all legislation save that pertaining to their individual enrichment, the desecration which is heaped upon them by the entire community.

THE BROOKLYN WATER-SUPPLY LABORATORY ABOLISHED.

WE regret to notice that the Rockville Center Research-Depot has been abolished by the Board of Health. It was established a little over a year ago, with infinite pains, by the then Commissioner of Health for Brooklyn, Dr. Emery, and was doing good work for the protection of the water-supply at a comparatively slight outlay of public money. It was the contention of Dr. Emery that the proper location for an institution of this nature is upon the watershed itself and that the chemic and bacteriologic researches should be accompanied by frequent inspections of all suspected feeders and ponds. The investigations have been conducted by Dr. H. Hill, formerly in the employ of the Louisville Water-Supply Commission, an expert in bacteriology, assisted by Dr. Ellms, chemist. Dr. Ezra H. Wilson, who recently resigned from the Health Department to give his sole attention to the work of the Hoagland Laboratory, was for a time in charge of the Rockville biologic work, but latterly was appointed to the honorary position of consulting bacteriologist. The names of these three officials are signed to an important report of two hundred pages setting forth the organization and results of the laboratory. This report is replete with tabular and other technical matters, and will be especially valuable to water-biologists and engineers; it may without exaggeration be characterized as a "State paper" of permanent value. As the new charter of New York City places the sanitary supervision of the water-supplies in the Board of Health, it is to be hoped, that this important function will not be slighted. It is beyond doubt a mistaken policy to neglect this line of sanitary work until the water becomes suspected or polluted, and popular panic and outcry, to say nothing of decimating epidemics, make its resumption necessary. It is true that there is a water laboratory belonging to the Water Bureau of the Borough of Brooklyn, but it is located remote from the water sources, being within the "city limits," near Prospect Park. That kind of a research-department, however, cannot be considered as competent to "fill the bill," and furthermore its position as an appendage to the Water Bureau—where quantity rather than quality is ever the criterion—is unfortunate from the sanitary standpoint. It is a relic of antiquated methods which does not inspire confidence.

"HOW TO ELEVATE THE PROFESSION IN THE COUNTRY."

WHILE the city physician is disturbed by the dispensary abuse, which threatens to take away his livelihood, his country brother is menaced, accord-

ing to a writer in the *Charlotte Medical Journal*, by a still more dreadful fate—self-extermination. This writer speaks especially of North Georgia and East Tennessee, where the customary fee for obstetric cases is $5, and other charges in about the same proportion. It is justly maintained that the larger the territory in which a man practises, the more difficult it is for him to keep up with his profession, and the writer tells us that we ought to express neither surprise nor resentment when we learn that one of his colleagues (a "Doc," as he calls him) attempted to perform craniotomy with his pocket-knife and a pair of rusty scissors. By and by Nature delivered the woman and the baby lived for a week before yielding to the effects of craniotomy.

One cannot help sympathizing with a writer who says: "I don't see how a physician can wait on a case of obstetrics aseptically and antiseptically, and keep his eyes on the case till all danger of septicemia is past for $5, the case being anywhere from two to eight miles from his office."

But even this sad condition has its remedy, and when the doctor returns with (out?) his V., he writes: "I believe that if the Legislature would pass a law making it a penitentiary offence for a physician to wait on a case of obstetrics for less than $10, in the country, they would do more to benefit humanity and to evolute the world toward what God intends it shall be than was ever done before at a single stroke."

ECHOES AND NEWS.

Mothers' and Babies' Hospital of New York.—It is reported that this vigorous young infant has secured a lease of the building owned by Dr. T. Gaillard Thomas and recently occupied by him as a private sanitarium.

Smallpox in the United States.—The Marine Hospital Service reports the existence of an epidemic of smallpox at Birmingham, Ala. One hundred and thirty-one patients with this disease are now under treatment at that place.

Damages for a Druggist's Mistake.—The Supreme Court of Brooklyn, N. Y., recently awarded a verdict of $5000 to a widow for the accidental poisoning of her husband by a druggist who sold oxalic acid for Carlsbad salts.

Sudden Death of a Physician.—The death by shooting of Dr. Charles B. Day of Glencoe, Minn., is reported by telegram. He was an alumnus, of the class of 1889, of the College of Physicians and Surgeons of New York.

A Brooklyn Appointment.—Dr. John Griffin has been appointed to a commissionership in the Brooklyn Department of Public Instruction, a position formerly held by him for many years. Dr. Griffin was for a period of four years the health-officer of that city.

The Meeting of the State Society.—The recent meeting of the State Society at Albany was marked by a large attendance, and the members evinced great interest in proposed medical laws, the Dispensary Bill coming in for a large share of their attention.

The Obstetrical Society of Cincinnati.—At a recent meeting of this society the following officers were elected: President, Dr. E. S. McKee; vice-president, Dr. W. D. Porter; recording secretary, Dr. Wm. Gillespie; corresponding secretary, Dr. M. A. Tate; treasurer, Dr. George E. Jones; librarian, Dr. Bonnifield.

A Celestial Remedy.—A "hedge doctor," a kind of quack in Ireland, was being examined at an inquest on his treatment of a patient who had died. "I gave him ipecacuanha," he said. "You might just as well have given him the Aurora Borealis," said the coroner. "Indade, yer honor, and that's just what I should have given him next, if he hadn't died."

A Free Supply of Diphtheria Antitoxin for the Sick Poor of London.—The London Metropolitan Asylums Board has resolved that a supply of antitoxin shall be placed in the hands of the medical officer of health under its control for free distribution to any general practitioner who may be called upon to attend and treat patients unable to obtain admission into the board's hospitals. The board has made arrangements for a supply of antitoxic serum from the laboratories of the Royal College of Physicians and Surgeons.

Cure for Hog Cholera.—The Chief of the Bureau of Animal Industry, Dr. D. E. Salmon, has submitted his report upon the experiments made in the treatment of hog cholera with antitoxic serum. The report shows the most encouraging results. The cost of the serum is only 10 cents per head for animals treated, and inasmuch as the losses from hog cholera are enormous it is proposed to ask Congress to appropriate funds to enable the department to furnish 2,000,000 doses of the serum during the coming year.

Resolutions upon the Death of Dr. O'Dwyer.—Resolutions upon the death of Dr. O'Dwyer have been placed upon the minutes of all the various institutions with which he was connected. Copies of these tributes have been received for publication by the MEDICAL NEWS. They are so similar in their character that their publication hardly seems necessary. The glowing tribute published in the MEDICAL NEWS of last week, together with the announcement of the resolutions above referred to, afford becoming recognition of the loss sustained by the profession in the death of Dr. O'Dwyer.

Quinin in India.—Brigade Surgeon Lieutenant-Colonel George King, of the Indian Army, has gained his reputation as Superintendent of the Royal Botanic Gardens at Calcutta, particularly in connection with the practical cul-

tivation of quinin. The British Government formerly imported yearly $250,000 worth of quinin until, after many experiments, Dr. King succeeded in the cultivation of the cinchona tree. There are now 4,000,000 trees in Bengal and every rural post-office in India sells a five-grain packet of the drug for half a cent, while the government makes about $3500 a year out of the profits.

Christian Science.—A "practitioner" of Christian Science of Kansas City, has recently been fined for not reporting a case of diphtheria to the Board of Health of that place. After a course of "Christian Science" the little patient having the disease died. The judge, before whom the case was tried, is reported to have said that "the methods of Christian Science in attempting to heal are frequently akin to murder." He might have gone a bit farther and said: "are murder," and then not have been very wide of the mark. The question is, how long will a civilized community tolerate this variety of baneful charlatanry?

Deaths after Christenings and Funerals in Winter.—At a recent London coroner's inquest the fact was brought out that in two cases children had died from pneumonia after having been taken to church to be christened. The coroner said he was in the habit of warning parents that all very young children should be most carefully wrapped up when they are taken out of the house, in winter weather, for any such purpose. Then, again, winter funerals are not without their dangers, as is pointed out by one of our contemporaries in the following paragraph: "Do not take off your hat at a funeral in winter when standing by the grave." At the funeral of Sir Frank Lockwood, M. P., a few weeks ago, another influential member of the Liberal Party, Mr. Charles Harrison, took cold and died within two days.

France Encourages Paternity.—The National Society for the Increase of the Population of France has just held an extraordinary meeting under the presidence of M. Jacques Bertillon. A resolution, adopted unanimously, was to the effect that as forty-seven of the General Councils of France had approved the program of the society, all electors at the coming general elections in the spring of 1898, and especially those who are the fathers of families, should be invited to demand of their candidates, to whatever political party they might belong, to inscribe in their program: (1) A reduction of taxation in proportion to the number of children; (2) the application of the same principle in all financial laws and in the succession duties; (3) the favoring by the State of large families from an administrative and military point of view.

Ambulance System in Jeopardy.—The ambulance system of the Borough of Brooklyn is in a position of uncertainty regarding its supply of the sinews of war. It is understood that the new charter of our greater city makes no provision for the appropriation that was for many years granted by the Board of Estimate. At seven of the hospitals ambulance stations are maintained at considerable cost, for the support of which the authorities have been in the habit of granting $1200 per annum. New legislation will probably be necessary to make it possible for this aid to be continued. The so-called city ambulances, three in number, were maintained by the health-officer at an annual cost of about $8000, inclusive of supplies. If the first interpretation of the new charter is correct there are no funds available for, or convertible to, the support of this branch of the public service.

Death-Rate of the Spanish Army in Cuba.—Inspector-General Losada, of the Spanish forces in Cuba, issued his official report about the middle of last month in which is indicated losses almost without precedent in modern times. His report shows that out of the 200,000 soldiers sent by Spain to put down the insurrection in the island from the beginning of February, 1895, to the beginning of December of the year just terminated, not more than 53,000 (a little over one-fourth) are at this moment fit for active service. The 147,000 are either dead or sent back to the motherland ill or wounded. The causes of this unprecedented death-rate and sick-list are (besides casualties in action) mainly three: (1) the inappropriateness of the clothing furnished to the European troops; (2) fatigue; and (3) lack of food. "The report, which does not apparently err on the score of reticence, paints a lurid picture of military service in the chief Spanish colony. Under successive generals the three-years' campaign, in spite of numberless Royalist "victories," leaves Cuba as precarious a Spanish possession as ever; while a whole generation must intervene before island and motherland alike can recover from the loss of blood, property, and treasures.

Yellow Fever and the Philadelphia Local Quarantine.—It was recently and quite confidently reported in the lay press of Philadelphia that yellow fever had succeeded in passing the Government Quarantine-Station at Reedy Island (see "Our Philadelphia Letter" of this week), in consequence of which the competency of the Marine Hospital Service to properly guard the City of Philadelphia from imported infections has been seriously questioned. That the report in question is fallacious we confidently believe, and not without good ground, as the following statement from Surgeon-General Wyman of the Marine Hospital Service will prove: "The Government Quarantine-Station at Reedy Island is located near the middle of the Delaware River. Occasionally the ice is so thick that it is impossible to board incoming vessels at this point, and at such times a medical officer is sent to board vessels in the harbor near Philadelphia from the revenue cutter. The local quarantine-station is situated at Marcus Hook some miles above the Reedy Island station. On January 19th the schooner 'Tingue' entered the harbor and was stopped at Marcus Hook, and it was stated by the Philadelphia papers that this vessel had cases of yellow fever on board. A medical officer of the Marine Hospital Service, an expert on yellow fever, was at once sent to make an investigation, and reported that 'the cases are not yellow fever.' Furthermore, the 'Tingue' would have been inspected by a national officer before being allowed to enter the port." Signed, W. WYMAN, Surgeon-General, Marine Hospital Service.

CORRESPONDENCE.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

A SENSATION IN QUARANTINE CIRCLES—ERADICATION OF BOVINE TUBERCULOSIS—CHARITY FOR WIDOWS AND CHILDREN OF DECEASED PHYSICIANS—PROFESSIONAL POLITICS AND THE HEALTH-OFFICER OF PHILADELPHIA—CONTROL OF THE EPIDEMIC OF ENTERIC FEVER—MENTAL CONDITION OF A YOUTHFUL MURDERER—DR. PEPPER'S ILLNESS—CÆSARIAN SECTION—CONGENITAL MALFORMATION OF GENITALIA—FIBROID TUMORS—TYPHOID FEVER ON THE INCREASE.

PHILADELPHIA, January 22, 1898.

QUITE *a sensation in local quarantine circles* was caused a few days ago by the arrival in the Delaware River of a vessel from a West Indian port with, it was said, yellow-fever cases aboard. Official reticence masks the true nature of the infection, but the general trend of public opinion stamps the infection yellow fever, particularly because of the fact that this disease is just at present epidemic at Jamaica, from which island the vessel hails. Yellow fever or not, the ease with which the ship managed to pass the lower river quarantine-stations to be finally held up by the State inspectors of vessels at a point just below the city has called down some caustic criticism upon the present régime at the Marine Hospital Quarantine Station in Delaware Bay, through whose fingers the fever ship slipped with so little effort. The incident illustrates, too, the fact that Philadelphia is none too well protected from the ravages of imported epidemics, and that our triple quarantine system is none too elaborate if the health of the city is to be maintained. [See "Echoes and News," page 150, for reply of the Marine Hospital Service.—ED.]

The report to the Department of Agriculture on the work carried on by Dr. Leonard Pearson, the State Veterinarian, and his associates, *in eradicating bovine tuberculosis and other contagious diseases of animals*, shows that during 1897, 16,000 animals were subjected to the tuberculin test, with the result that 2500 were condemned as tuberculous and killed. The same report also shows that equally important work has been done by these officials in dealing with the recent local outbreak of anthrax in the western part of the State, and that thorough investigations have been pursued for the purpose of eradicating rabies, hog cholera, and other animal infections.

At a meeting to be held on January 26th, at the College of Physicians, the members of the Mutual Aid Association of the Philadelphia County Medical Society hope to arouse a more general interest among both the medical profession and the laity in the efforts being made by the association *in extending the hand of charity to the indigent widows and families of deceased physicians*. At this meeting Dr. Charles A. Leale, President of the New York Society for the Relief of Widows and Orphans of Medical Men, will give an account of the work pursued by that body; Dr. A. F. Currier of New York will deliver an address on "The Fifty-five Years of the New York Society for the Relief of Widows and Orphans of Medical Men." Other prominent speakers of the evening will be the Rev. Dr. Charles Wood, the Rev. Dr. Joseph Krauskopf, and Drs. Edward Jackson, Charles Hermon Thomas, and John B. Roberts. At the close of the meeting a reception will be tendered the invited guests by the Association, at the University Club.

At a business meeting of the Philadelphia County Medical Society, held January 19th, the following important resolution, *apropos* of the *fight now being made to divorce from professional politics the position of Health-Officer of Philadelphia*, was adopted: "*Resolved*, That the Philadelphia County Medical Society believes that the best interests of the City of Philadelphia and of the State of Pennsylvania will be conserved by the appointment of an educated physician as Health-Officer. *Resolved*, That the secretary forward to the Governor of Pennsylvania a copy of this resolution, with the request that he give thoughtful consideration to the opinion of the society thus formally expressed." Regarding the necessity for taking *immediate steps to control the widespread epidemic of enteric fever* now prevailing in this city, the society "*Resolved*, That a committee be appointed to wait upon the mayor and councils and urge the necessity of immediate steps for the filtration of the water-supply of the city, in view of its responsibility for the prevalence of typhoid fever in the city." The society then took up the question of the publication in a medical periodical of its proceedings, and it was voted to enter into a contract for the present year with *The Philadelphia Polyclinic* by which this journal, on mutually advantageous terms, is to undertake the publication in its columns of the proceedings of the society, at regular intervals. The contract of a similar nature heretofore existing with *The Medical and Surgical Reporter* was abrogated. The following officers for the ensuing year were elected: President, Dr. Edward Jackson; first vice-president, Dr. S. Solis-Cohen; second vice-president, Dr. John H. Musser; secretary, Dr. John Lindsay; assistant secretary, Dr. Elwood R. Kirby; treasurer, Dr. Collier L. Bower; censor, Dr. William M. Welch. Six new members were elected, and the names of thirty-seven candidates for membership were reported favorably by the Censors.

Drs. Thomas J. Morton and John B. Chapin, the well-known alienists, have been appointed by the Court to *examine into the mental condition of Samuel Henderson, the fifteen-year-old murderer*, the revolting details of whose crime has already been given wide publicity by the daily press. The inquiry into the matter is to begin at once, and it is thought that the expert report rendered will largely influence the course to be taken by the authorities when the case comes to trial.

DR. WILLIAM PEPPER, *who has lately been confined to his house with an attack of la grippe*, has so far convalesced that he is able to undertake a journey to the South where he expects to fully recuperate. During his absence Dr. Alfred Stengel is filling the Chair of Practice of Medicine in the University of Pennsylvania.

The condition of Dr. Theophilus Parvin *is so serious that grave doubts of his recovery are expressed*. It is said that recent vesical complications and pulmonary

edema have supervened to complicate the renal lesions from which he suffers. The lectures on obstetrics at the Jefferson Medical College are being delivered by Dr. Edward P. Davis, during Dr. Parvin's absence.

The appointment of Dr. W. E. Robertson *as demonstrator of bacteriology* in the Medico-Chirugical College is announced.

Commencing with the current number the *International Medical Magazine is to be published under a new management.* The editorship of this journal, formerly under the charge of Dr. Henry W. Cattell, has been assumed by Dr. Walter L. Pyle. It is understood that the general plan and scope of the *International* will remain unchanged.

At the last stated meeting of the Section on Gynecology of the College of Physicians of Philadelphia, held January 20th, Dr. G. M. Boyd read a paper on *Cæsarian section a second time, because of contracted pelvis—Cæsarian section, because of coxalgic pelvis.* Dr. J. M. Baldy presented a communication on *congenital malformation of genitalia*, and described a case in which absence of uterus and adnexa were associated with a rudimentary vagina, in a young woman, otherwise perfectly developed, and who had never menstrated; the speaker also made some *remarks on fibroid tumors*, and exhibited specimens of such growths. Dr. J. B. Shober reported a *double celiotomy for appendicitis and retroversion of the uterus*, in which he first did an operation for the excision of a diseased vermiform appendix, and then an abdominal section in the median line to correct a retroverted uterus by the method of ventral suspension; the patient made a good recovery, although for a time obstinate and serious intestinal paresis was present.

Despite the efforts of the Board of Health and despite the fact that the general sanitary condition of the city is reported good, *typhoid fever is on the increase in the infected districts*, and has begun to spread more generally through other parts of the city. It is conceded by all that the cause of the epidemic is the pollution of the water-supply. The new cases of typhoid for the week ending January 22d, numbered 212, as against 201 for the preceding week. The deaths from this cause reached a total of 23 cases, or 6 more than reported last week. There were 119 new cases of diphtheria reported, or 23 more than last week, with 20 deaths; and 62 new cases of scarlet fever, exactly the same number that occurred last week, with 2 deaths. Of the 461 deaths from all causes during the past week 147 were of children under five years of age.

OUR BERLIN LETTER.

[From our Special Correspondent.]

GERMAN MEDICAL OPINIONS ON ROTHELN—THE PRESENT STATE OF CLINICAL HEMOGLOBINOMETRY—PROFESSOR GERHARDT ON THE GRUBER-WIDAL-SERUM REACTION IN TYPHOID—PROFESSOR SALKOWSKI AND THE XANTHIN BODIES IN THE URINE.

BERLIN, January 20, 1898.

GERMAN measles, "*Rötheln*," occurs just often enough in America to make opinions as to its etiology and contagiousness interesting. Some recent opinions on the matter from Dr. Blaschko, whose opportunities for observations of the disease have been excellent, appeared in the last number of the *Therapeutische Monatshefte*, and his opinion seems to be more or less that of the profession here generally. Rötheln is not considered to be an independent disease with a specific etiology of its own, though this is not a universal opinion. The bacterial cause of measles is, of course, not as yet known, but it is considered that when it is discovered it will be found that rötheln is caused by a degenerate form of the bacterial cause of measles. As to contagiousness, Dr. Blaschko does not consider that the liability to contagion, even for the immediate members of the family, is sufficient to require isolation of the patient. He considers that other children of the family may be allowed to continue attendance at school without endangering their fellow pupils. Epidemics of rötheln spread in this way, it would seem, have not been observed in Germany.

As to treatment, all the indications are met by a bland diet, rest in bed during three to four days, and a weeks' confinement to the house. After two weeks the patients may resume attendance at school. Complications, Dr. Blaschko has never seen, and when they are reported to have occurred he believes that the cases were not really what should be called rötheln, but rather genuine measles, or at times scarlet fever.

The present position of the clinical pathology of the blood is strikingly unsettled, or at least would appear so from the rather varied and generally unsatisfactory positions taken by prominent clinicians. Grawitz is giving a course of lectures on blood pathology from the clinician's standpoint, which represent, I suppose, some of the best and most advanced scientific thought of the day on the subject. He never talks of the estimation of hemoglobin by any of the old methods. Notwithstanding all the ingenuity spent on supposed instruments of precision, and recent supposed important modifications of them, one never hears of either the instrument of Fleischl or Gowers, but always of the dried substance of the blood, *i.e.*, of the weight of the residue remaining after evaporation.

The use of this method shows at least one thing very clearly: that the blood plasma undergoes much greater change during the course of certain blood diseases than has usually been thought to be true. In chlorosis, for instance, the ratio of watery constituents in the cells and in the plasma of the blood does not always show coincident changes from the normal. Usually the amount of watery constituents of the cells is proportionately much greater in chlorotic conditions than that in the plasma. This holds true, as a rule too, for pernicious anemia, but there are cases of both affections in which the plasma shares in the hydremic change, and these cases are of especially bad prognosis. It seems probable that the near future will see certain changes in the ordinarily accepted division of blood diseases as at present taught, the modications being founded on the important changes in the plasma which are not yet systematized.

Professor Gerhardt, in talking of the *estimation of hemoglobin*, recently said that so much discredit had been

thrown on ordinary methods of estimation that the practitioner scarcely knew what to adopt. He suggested that the simple test of Professor Martins is probably as good as any until the clinical-blood pathologists have settled among themselves whether instrumental color hemoglobinometry, the weighing of the dried substance of the blood, or the estimation of the specific gravity of the blood, is to be regarded as the best test of its hemoglobin contents.

Professor Martins places a drop of blood from the patient upon a handkerchief, and beside it, a drop of normal blood. A little experience enables one to judge with sufficient exactness for all clinical purposes how much the hemoglobin is reduced in the pathologic specimen. A series of specimens may be kept for some time for comparison, and the degree of improvement in the chlorotic condition fairly judged.

Professor Gerhardt's opinion, by the way, of what is called very generally here in Germany the *Gruber-Widal reaction in typhoid fever*, does not concede to it much practical value for the practitioner. The precise precautions necessary for its proper use, the fresh typhoid culture, the careful exact dilution, he thinks almost impracticable for general employment. Then, in many cases, the patient's history cannot be obtained with sufficient exactness to be absolutely sure about preceding attacks of typhoid, and besides the possibility of a second attack cannot be excluded in such cases. In certain cases even normal serum gives the reaction, while in certain others the reaction does not occur at a period sufficiently early in the disease to make it of diagnostic value.

On the whole, while its positive presence is not always conclusive, a negative reaction is not absolutely exclusive for typhoid. It is only in certain crucial cases that such a diagnostic aid is required, but in these cases surrounding circumstances are, as a rule, so dubiously significative that it is only an absolutely pathognomonic sign that is of practical value. As it is, the Gruber-Widal reaction gives no more assurance for the diagnosis than does the Diazo reaction, and that, after a period of enthusiastic popularity, has sunk into almost complete desuetude. What Professor Potain called some time ago the diagnostic problem of the end of the century—a means of diagnosing with certainty doubtful cases of typhoid fever still remains to be solved.

It has been known for some time that Professor Salkowski, in the chemical laboratory of the Pathological Institute, was at work on tests for the exact determination and *the significance of the xanthin bodies in the urine.* Since Horbaczewski's ground-breaking work with regard to the fate of the metabolic products of the cell-nuclei, especially of the nuclei of the leucocytes, the subject of the xanthin bodies has attracted a good deal of attention. The demonstration that uric acid and the xanthin bases are the end-products, not of systemic nutritional metabolism, but of tissue metabolism, especially of the leucocytes, was one of the most important steps of late years toward the solution of the mysterious processes of vital chemism.

According to Horbaczewski, there is a complete parallelism between the number of leucocytes and the amount of uric acid and xanthin bases excreted in the urine. Not long ago the whole field of physiologic and pathologic leucocytosis lay temptingly open, and soon a number of articles appeared on this subject. Most of them were not encouragingly scientific, and some were neither consistent with themselves nor with others along the same line. Something of the fault lay with the present tests for the xanthin bodies in the urine, and the inadequate means of separating them with certainty from uric acid and its derivatives, so that further work from a practical scientific chemist was eagerly anticipated.

Meanwhile, Neusser's description of the perinuclear basophilic granulations of leucocytes—the little bodies surrounding the nucleus which stained with triple stain are of a blackish blue—added to the interest of the question of nuclear metabolism, while diverting it to another phase of the process. These little bodies, evidently products of nuclear metabolism, some one of the steps perhaps of the oxidation processes which are known to connect nuclein with uric acid, might give important data for the solution of the questions at issue. Then Kolisch, working in Neusser's clinic in Vienna, claimed to have found a constant relation between these perinuclear basophilic granulations and the xanthin bodies in the urine. He even considered that the so-called uric-acid diatheses are not due to uric acid, or at least are not connected with variations of excretion of uric acid in the urine, but with the amount of the xanthin bodies. Gout, in other words, is not a manifestation of a uric-acid diathesis, but, so to speak, of a xanthin base diathesis. This part of his work has not only not been confirmed, but would seem to be thoroughly disproved. The interest in the xanthin bodies remained, however. Professor Salkowski's article in a recent number of *Pflügger's Archives for Physiology* will be eagerly welcomed. His silver method of precipitating the xanthin bodies and of separating them completely from uric acid would seem to fill the long felt want. While other tests have given extremely large amounts of xanthin as present, and besides have shown extensive variations in supposedly healthy individuals where no reason could be found for it, this seems to give regular reliable results. The percentage of the xanthin bodies to uric acid present is much smaller than has been given by other workers. On the whole, Professor Salkowski does not think that these bodies deserve as much interest as has been devoted to them, and considers that important conclusions as to nuclear metabolism and the chemic vital processes of nuclear life do not lie hidden in our lack of knowledge of these bodies.

ADVANTAGES AND DISADVANTAGES OF MASSAGE IN THE TREATMENT OF FRESH FRACTURES — EARLY DIAGNOSIS OF TUBERCULOUS AFFECTIONS OF THE CHEST BY THE AID OF SKIASCOPY—GASTRO-ENTEROSTOMY FOR ULCER OF THE STOMACH —THE HOSPITAL CONTAGION OF TYPHOID FEVER—PROTEOLYTIC POWER OF THE DUODENUM.

LUCAS-CHAMPIONNIERE showed before the Academy of Medicine, December 21, 1897, a young man who had

sustained a comminuted fracture of the lower end of the humerus, the result of a fall. The first four days after the injury the arm was put in a splint; then it was kept in a sling only, and after eighteen days even this was discarded. From the very first day *there was a daily application of massage*, and as soon as the union was sufficiently firm there was also daily passive motion. Recovery was perfect. This surgeon holds to the idea that immobilization, far from favoring the repair of the tissues, as was formerly believed, in reality retards it. See stated that massage is useful in the treatment of fractures because it increases the activity of the absorption of the effusion, as union of the bone cannot take place until after this absorption is complete. The same end may be obtained more rapidly, and with less difficulty than by massage, by the application of a rubber bandage. Pean said that massage ought not to be employed from the first except in those cases of fracture in which there is no displacement of the fragments. In most fractures some immobilizing apparatus is necessary for a time, in order to maintain perfect reduction. It is only after such preliminary treatment that massage is permissible in these cases.

Kelsch spoke of the *early diagnosis of tuberculous affections of the chest by the aid of radioscopy*. His observations were based upon the examination of 124 young patients with various thoracic diseases, thought clinically to be non-tuberculous. The result was negative in 73 instances. In 51 patients the apices of the lungs were found to be less permeable, and transmitted the rays less readily than in the normal, or the glands of the posterior mediastinum, or the pleura, were thickened, and there was partial ankylosis of the diaphragm. As these regions are those in which tuberculous processes begin it is reasonable to suppose that at least in some of these cases tuberculosis existed. This is in accord with the deductions reached through autopsies, *viz.*, that from 20 to 45 per cent. of young subjects present latent tuberculous lesions.

Renaut illustrated by photographs, December 28th, the ease and certainty with which a differential diagnosis may be made between syringomyelia and rheumatism of the hand when the Röntgen-rays are employed.

Walther, Ricard, and Kirmisson at the session of December 22d, described cases in which large cysts of the neck were removed, expressing the opinion that such cysts are of a venous rather than of a lymphatic origin as is usually supposed to be the case.

Tuffier announced that he had three times performed *gastro-enterostomy for ulcer of the stomach*. Two of the patients so operated upon recovered. One died from septicemia starting from a gangrenous focus in the liver due to the gastric ulcer, inflammatory changes having glued these two organs together. The reason for operation in this case was uncontrollable hematemesis, as it was in one of the successful cases. In the third case there was thought to be a perforation, but at operation it was found that the symptoms were due to localized peritonitis caused by the ulcer, although the stomach wall had not given way. The good results which follow gastro-enterostomy in such cases are perhaps due to the complete rest given the stomach, and also to the fact that food is retained in this organ only a short time.

At the session of December 29th, Hartmann stated that he had once performed gastro-enterostomy for hematemesis. Vomiting of blood ceased, but the patient died several days later. As far as known, this operation has been performed in 12 such cases, the result being 4 recoveries and 8 deaths. This is not very encouraging, and when one considers that immediate death from a large hemorrhage is rare, and that patients often recover when treated by means of decubitus, restricted diet, and ligatures to the limbs, it is doubtful if the operation is one to be recommended.

At the Medical Society of the Hospitals, December 17th, Netter spoke of the *hospital contagion of typhoid fever*. From 1892 to 1895, 27 cases of typhoid fever developed in the Trousseau Hospital. Twelve of these cases were in nurses, and of these 10 were on the night force. In one case, which recently occurred, the proof was conclusive that the contagion was the result of contact with linen soiled by typhoid dejecta. These cases seem to conclusively prove the contagiousness of typhoid fever, but it does not seem necessary on this account to isolate patients having this disease.

Lemoine mentioned an instance in which there was only a single typhoid-fever patient in the hospital ward; nevertheless, several patients convalescent from acute articular rheumatism all developed typhoid fever. As these patients made use of the same bed-pan, it seemed probable that the disease was transmitted in this manner. Œttinger mentioned a similar instance in which transmission of contagion seemed to have occurred from the infected tip of a fountain-syringe used for all the patients. The infection was not necessarily direct through the rectum, but more likely through the soiling of the hands of the attendants with the fecal matter. Several members of the society narrated similar instances.

At a session of the Biological Society, December 18th, Pachon described experiments by which he had proved that the *duodenum possesses a digestive power of its own with respect to albumin*. If thirty cubic centimeters of coagulated egg albumin be introduced into the duodenum of a fasting dog and kept there by means of ligatures, it will be almost completely digested within six hours. If, before it is introduced, the duodenum is roughly handled so that submucous ecchymoses are produced it will not be digested at all. This shows that the digestion cannot be attributed to the pancreatic juice, but is the result of the proteolytic action of the duodenum itself.

Vienna.

BACTERIOLOGIC ORIGIN OF TYMPANITES UTERI—RESULTS OF OPERATIVE TREATMENT OF LUPUS—MECHANICAL TREATMENT OF OBESITY — TEMPORARY UTERINE DISPLACEMENT POSSIBLY DUE TO MUSCULAR CONTRACTION.

At the Imperial Royal Society of Physicians, December 10th, Lindenthal discussed *bacteriologic investigations in tympanites uteri*. This condition was formerly supposed to be due to putrefaction of the embryo. It has, however, been observed while the embryo still

lives, and is at present regarded as of microbic origin. It has been sometimes ascribed to the action of the coli bacillus, although this microbe is not capable of producing gas except in the presence of sugar. In four cases of tympanites of the uterus, Lindenthal demonstrated the presence of different organisms. In every case, however, he found an anaerobic bacillus which was capable of producing gas in large quantities in a short time, and seemed to be related to the bacillus of malignant edema.

At the session of December 17th, LANG pointed out the *good results which may be obtained by the operative treatment of lupus.* Of thirty-five patients whose histories he followed for several years, twenty-seven were permanently cured. The various methods of covering defects by means of flaps give more permanent results than Thiersch grafts; for, although the immediate results of the latter method are most satisfactory, yet the subsequent shrinkage of the grafts may cause trouble.

At the College of Doctors of Medicine, December 6th, WINTERNITZ spoke of *mechanical cures for obesity.* Banting's cure consists in an almost exclusively albuminous diet. Ebstein allows a certain amount of fat. These and other similar methods are starvation cures, and it is questionable whether such can be carried out without injury. Thyroid extract reduces the fat by hastening the combustion of the intermediate products of metamorphosis. This would be the ideal treatment if it too were not accompanied by disturbances of the general system. There are, however, purely physical methods for increasing the combustion of fat; one of these is increase of muscular activity. If this is pushed to a degree, the temperature of the body is raised, anemia results, and there is a reduced capability of exertion. This may be avoided by artificially cooling the body before the muscles are called into play. If a patient is treated for several days with cold sponge baths, followed by steam baths, the skin is soon brought into such a condition that this increase of temperature is avoided. Profuse excretion of sweat also assists in reducing the fat. After the steam bath the patient takes a bath in a tub, and then the prescribed walk. Later massage is administered. This series of manipulations may be repeated twice, or in some cases, three times daily. After the steam bath some patients are at once put into a cold tub-bath. By this treatment Winternitz, within a few weeks, can bring about a loss in weight of forty-five pounds without weakening his patient and without altering the diet to any great extent.

At the session of the Medical Club of December 15th, SCHUTZ stated that in certain cases backward displacement of the uterus disappears spontaneously. This suggested the thought that the *uterus might be temporarily displaceed by spastic contraction of certain muscles.* While there is no clinical evidence to sustain this idea it appears that Douglas' pouch is sometimes of such form that muscular contraction would be able to draw the uterus backward.

Camphor as an Antigalactagogue.—HERRGOTT reports a remarkable diminution in the secretion of milk as a result of the employment of camphor internally in 3-grain doses, three times daily for three days.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninety-Second Annual Meeting, Held at Albany, N. Y., January 25, 26, and 27, 1898.

FIRST DAY—JANUARY 25TH.

MORNING SESSION.

THE meeting was called to order by the President, SENECA D. POWELL, M.D., of New York, after which prayer was offered by the Rev. Charles A. Richmond of Albany. The President then delivered his

INAUGURAL ADDRESS,

in which he said in part: In inaugurating your Ninety-second Annual Meeting, it becomes my pleasant duty to report that the affairs of the Society throughout the State are prosperous, and that the same excellent conditions reported by my predecessors continue at the present time. We are united in our brotherhood, contented with our affiliations, honored in our government, and enjoy the blessings of harmony. The only shadow which has fallen upon us is the shadow of death, twelve of our fellow members having died during the past year.

The Merrit A. Cash Prize, as at present applied, is of no advantage to the Society, and some steps should be taken to utilize it in a practical manner.

The work of the State Board of Examiners in controlling the practice of medicine shows that there has been no negligence on its part in endeavoring to maintain the standard of the profession. Of the 862 candidates for license to practise who have been examined, 627 were accepted and 235 rejected, an average of about twenty-two per cent. This would also show that the standard of our medical colleges has been raised. No worthy man is debarred from practice.

The law in regard to the sale of poisons is defective; for not a day passes but the daily papers contain reports of one or more deaths from carbolic-acid poisoning, the drug having been taken by mistake, and suicides by this agent are of frequent occurrence. The Medical Society of the State of New York should see that the people are protected not only from criminal intent, but from the impulse of self-destruction which comes to those so burdened that they know not which way to turn.

I hesitate to recommend any new legislation; for, as a rule, the less governed we are, the better. It is our duty to protect the sick and suffering, rich and poor, not only from the quack and charlatan but from the ill-educated doctor who cares nothing for science and practises medicine with none but pecuniary ends in view.

The annual report of the treasurer was then read. The receipts during the year amounted to $5558.63; disbursements, $2680.98; balance on hand, $2877.65.

The annual report of the Committee on Legislation was also read. The report detailed the work of that committee during the past year, it having chiefly consisted in successfully opposing bills which, becoming laws, would have been harmful to the profession. Among them was

the Optician's Bill, and the attempt of the New York State Medical Association to obtain representation in the State Board of Medical Examiners. The bill exempting from examination practitioners from other States who desire to practise in the State of New York was defeated, as was also the bill providing for a State Veterinarian, thus retaining the examination and sanitary supervision of cattle in the hands of the State Board of Health. The bill abolishing the office of coroner and the Dispensary Bill, in regard to which the committee exerted itself to secure favorable action, failed to become laws. The Midwifery Bill and the bill for the regulation of expert testimony were not presented in time to be acted upon by the last legislature.

The annual report of the State Board of Medical Examiners was then read:

The report of the Regents' Office on this subject as annually presented to the public is a *résumé* of the work of the academic year ending July 31st of each year. The following figures, therefore, unless otherwise stated, bear upon the academic year ending July 31, 1897:

Total number of candidates, 862; accepted, 627; rejected, 27.2 per cent. State Board, 801; accepted, 580; rejected, 27.5 per cent. Homeopathic Board, 47; accepted, 37; rejected, 21.2 per cent. Eclectic Board, 14; accepted, 10; rejected, 28.5 per cent.

Five examinations were held during the academic year, *viz.:* in September, 1896; January, April, May, and June, 1897.

Since September 1, 1891, 37 examinations in all have been held, and from a list of 3290 candidates, 3102 were examined; of these latter 2399 were duly licensed, the total rejections being 703, or 22.68 per cent. The average rejections for the above period were as follows: State Board, 19.3 per cent.; Homeopathic Board, 16.5 per cent.; Eclectic Board, 26.7 per cent.

Most of the rejected candidates have subsequently been reexamined, in some cases repeatedly, as evidenced by the fact that of the 3103 examined only 181, or 7 per cent., have eventually failed to secure a license. Since September 1, 1891, 1192 physicians have applied for endorsement of their credentials under the several exemptions in the law providing for the correction of a legal registration, of which number all but 143, or 12 per cent., furnished satisfactory legal claim to such right. The figures as above given are an indication only as to the results obtained by those who *a priori* were fitted to enter the examinations. This entrance test in itself has been of sufficiently high standard to debar many persons from even being admitted to our examinations. Hence, it will be safe to assume that more than 30 per cent. of those who actually applied and of those who were actually examined were refused even admission to examination for licenses to practice.

The total number of candidates examined during the year who were graduates of New York institutions was 545, and it is a pleasure to again be able to make the statement that their examination papers were more satisfactory than those which were presented by graduates of medical schools outside the State, the ratio being as two to one.

A clause in the law permits New York State's Boards of Medical Examiners to endorse licenses obtained in other States whenever the requirements of New York State shall be equalled in all particulars. Up to the present time we have felt ourselves unable to recommend the endorsement of licenses obtained in other States because, although in many the New York standard is approximated, the preliminary requirements as well as the rigorous system of examinations here do not obtain. We do not care to lower our standard. The Medical Society of the State of New York has placed itself on record as opposed to any such step, and the lawmakers up to the present time have conformed to its wishes in this particular, considering it unfair to our own graduates to admit licentiates from other States on lower general standards than are required of our own candidates. A proposition has been made, however, to amend the law so that reciprocity may be carried on between States where, because of the non-existence of the excellent safeguard possessed by us in our Regents' body, similar tests cannot be applied by such States. The substance of the proposal is that each case be judged upon its individual merits, thus: A candidate from another State presented himself to the Regents for the endorsement of a license shall prove (1) that he has the preliminary academic requirements; (2) that he has attended four full courses of lectures at a school of medicine recognized by this State as of good standing; (3) that he was licensed by a State Board of Medical Examiners whose examination-tests are equal to ours; (4) that we have access to examination-records to prove that he was properly marked as proficient; (5) that the methods of examination conducted at the time he applied for a license in a foreign State were properly safeguarded. It is the belief that it would be only the part of justice to endorse the license of such an one. At the present time we are charged with undue severity in this particular, and a willingness on the part of those interested to consider this question in all its bearings would show that at least we are open to conviction. It is a cause for congratulation that all the medical colleges of the State have displayed commendable zeal in elevating their standards, prolonging their courses of study, and adding to their professorships.

Fifteen invited guests were present, and upon resolution were welcomed to all the privileges of the meeting.

DR. WEY, Chairman of the Committee on By-Laws, reported adversely upon an amendment proposed at the last meeting to change the place of meeting of the Society to New York City, Buffalo, and Albany, alternately, and the time of meeting to the first Tuesday in February. This amendment was thoroughly discussed later in executive session, and was lost by a standing vote of 35 to 40. Albany will, therefore, continue to be the Mecca of the Society.

DR. WENDELL C. PHILLIPS of New York County read a paper, entitled

EAR MANIFESTATIONS IN GENERAL DISEASE.

The author said that although all diseases, especially the exanthemata, which lead to a debilitated condition

are apt to be accompanied or followed by ear manifestations. The subject has received but little attention. Cases were cited in which middle-ear disease accompanied malaria, syphilis, neurasthenia, scarlet fever, etc., and one was mentioned in which the ear trouble simulated the symptoms of typhoid fever. Adenoid growths in the pharynx was given as a frequent cause of middle-ear disease and consequent deafness, and statistics were quoted to show that many deaf mutes have such adenoid growths. Carious teeth was also mentioned as a cause of ear complications. The author showed a new ear speculum and electric light combined, which had been devised by Dr. Nichol of New York.

DISCUSSION.

DR. LUCIEN HOWE of Erie County: I cannot let this excellent paper pass without some word of comment to emphasize what has been said about the importance of ear manifestations in general diseases. The terrible results which follow neglect in cases of this kind should make us very careful not to overlook the condition. It is in the beginning that treatment will accomplish the best results.

DR. HOLT of Portland, Me.: In scarlet fever the ear should always be treated, and an ear affection arising at this time should never be allowed to continue until it becomes chronic. The time to treat the ear is when the discharge begins. The ear is sometimes involved in cases of Bright's disease, but, in such instances, little relief can be afforded. During the course of the acute diseases of childhood the general practitioner should always give attention to the ear.

DR. JOHN O. ROE of Monroe County then read a paper upon

CASES OF ACUTE NON-DIPHTHERITIC INFLAMMATION OF THE LARYNX REQUIRING THE PROLONGED RETENTION OF THE INTUBATION-TUBE.

The paper gave in detail the case of a child, thirteen months old, who was attacked by a slight croupy cough, apparently the result of a cold. There was some difficulty of respiration, which increased to such an extent that on the third day an intubation-tube was introduced. It was then thought that the child was suffering from laryngeal diphtheria, but repeated bacteriologic examination did not show the Klebs-Löffler bacillus, although numerous micro-organisms were found. The tube was worn during six weeks on account of the dyspnea, being repeatedly expelled and re-inserted.

A similar case, occurring in a little girl three years of age, was also cited. Complete recovery followed in both instances, but there was hoarseness and aphonia for a time after the removal of the tube. The author referred to two cases occurring in the practice of the late Dr. O'Dwyer, in which the tube was worn respectively ten and eleven months. Both of these were cases of diphtheria.

THE REPORT OF A CASE OF UNUSUAL CONTRACTION OF THE VISUAL FIELD AND DISORDER OF THE COLOR SENSE FOLLOWING AN INJURY,

was the title of a paper read by DR. T. F. C. VAN ALLEN of Albany County.

The patient was a man twenty-six years of age, a painter, who while at work was thrown from his scaffold by the breaking of a rope. He sustained a dislocation of the right shoulder, a fracture of the right humerus, and a cut on the head. There was no evidence of fracture of the skull. The eyelids became swollen and ecchymosed after the accident, but the vision seemed good. The patient made a slow recovery. Five weeks after the injury he found that in reading his eyes became tired within a few minutes, and that the text appeared blurred. Six months after the accident he was not able to distinguish colors, and, on this account, came under the speaker's observation. Examination showed that the intra-ocular tension was not increased; R. V. 20/40; L. V. 20/30; neither pupil responded to reflected light until the mirror was brought very close to the eye. There was considerable contraction of the visual field. His perception of red was good, but he could not distinguish blue from green. The man was of good habits, so alcoholic and tobacco amblyopia were excluded. Therefore, the author considered the condition due to the concussion and nervous shock resulting from the fall. Examination four years after the accident showed R. V. 20/30; L. V. 20/30; the visual field for white and yellow was increased; field for blue and green defective; field for red not very far from normal. He sees fairly well, but has difficulty in matching colors in a dim light.

DR. C. B. HERRICK of Rensselaer County, then read a paper, entitled

THE RAILWAY SURGEON AND HIS WORK.

The railway surgeon has become a specialist because of a demand for special services in this line. In the United States more than a million men are employed on railroads and of these 40,000 are injured annually. The injuries which the railway surgeon is called upon to treat differ from others in that they have been inflicted by enormous weights in motion, the crushing force of which is tremendous. The degree of severity of the injury depends largely upon the speed of the object which causes it, a train going at a slow rate of speed causing a crush, whereas one going faster will limit the injury to the wound itself. Owing to the elasticity of the skin it is possible for a train to pass over a man's leg without causing any external wound, and the general practitioner is often misled into to thinking that no serious injury has been inflicted, when in fact, it is so great as to frequently impair the tissues to such a degree that vitality is lost and repair impossible. The railway surgeon is conservative, especially when injuries of the upper extremities are concerned. When the lower extremities are involved it is possible to be too conservative. As the men employed on railroads usually have families dependent upon them, it is impracticable to subject them to prolonged treatment in the effort to save a crushed foot, and in such a case it is better to amputate at once. In amputating it should always be remembered that an artificial limb can usually be best fitted in proportion to the length of the stump. The conditions met with in the work of the railway surgeon are favorable to sepsis. The hand of the railroad man is cov-

ered with oil and cinders, and dirt of all kinds is often carried into a wound at the time of infliction. Accidents, too, are apt to occur in unfrequented places and often in inclement weather, all of which reduces the chances for recovery. Railway surgeons were first employed in the West where hospitals are widely separated, and now they are found all over the world. It has also been recognized that prompt attention to wounds is all important; therefore, emergency packets have been placed upon all trains to be used by a physician if there is one at hand, if not, by one of the train-hands, all of whom have been taught what to do in emergencies. They have also been instructed as to the best way to transport an injured man. On some roads a hospital-car is provided which at all times is kept in readiness to go where it is required.

The railway surgeon is constantly considering the proper sanitation of cars, recognizing as he does the great danger of infection being carried in this way. The examination of employees as to their fitness is also one of his duties. There are six thousand railway surgeons in the United States.

A paper, entitled

THE RIVALS OF THE PHYSICIAN IN PRACTICE,

was read by REYNOLD W. WILCOX, M.D., of New York County.

Considering the conditions under which medical men work, the author said, it is not surprising that they have so much to complain of. It is hardly realized how many hangers-on and camp-followers there are. This is probably due to what is said to be the American love of a title; there are many who want to be called "Doctor," and, if they cannot reach that height, some of them are willing to be dubbed "Doc." All medical men are familiar with the "Doc" of the corner drug-store—the prescribing apothecary who repeats prescriptions without the physician's permission, who gives to somebody else a prescription originally given to a different person, who substitutes preparations of his own manufacture for those ordered in a prescription. It seems as though such "physicians" will continue to increase in number to the end of time. There seems no way to confine the labors of these people to the legitimate business of compounding physicians' prescriptions. Then, again, there is the instrument-maker, but he has learned that a truss will not accomplish much for the patient when placed over a bubo or an undescended testicle. Of late years the physician has had to contend with the trained nurse, who prescribes for the members of the family of her patient, and the massage operators and bath attendants, who are always ready to give advice. Curiously enough, the veterinary surgeon is the only individual who will not prescribe for a human being, in spite of the fact that he is much better able to do so than many who do. The reason of all this is found in the fact that the physician works in an altruistic way, thinking only of the good of the people and not recognizing the commercial side of his affairs.

AFTERNOON SESSION.

DR. JOHN H. PRYOR of Erie County read a paper, entitled

WHAT SHALL THE STATE AND COUNTY DO FOR THE CONSUMPTIVE?

In the State of New York 13,000 persons die of consumption every year. In Buffalo alone the annual death-rate from this disease reaches nearly 500. These figures show the frightful loss of life due to tuberculosis and the necessity for measures which reduce the death-rate. Besides those who lose their lives, many are incapacitated by this disease. The popular belief that tuberculosis is an incurable affection is incorrect. Intelligent treatment, instituted early, and proper environment, will accomplish much in cases of incipient consumption, The well-to-do victims of tuberculosis seek change of climate, and thereby gain the best chance of recovery. The majority of the cases occur among the poor, and they are the real sufferers—struggling along until they can no longer work and then seeking relief. Special hospitals for these patients should be established in which they can have pure air, sunlight, and space for indoor exercise when advisable. Open-air life and nourishing food will be the means of cure in many cases of incipient consumption. Such a hospital should not be connected with an almshouse, as was recently attempted at Buffalo; it should be situated where the most beneficial climate can be obtained, and in this State there is none better than that of the Adirrondacks. Ill-managed charity ignores the class of cases in question, while provision has been made for poor persons suffering from other diseases. It is the duty of the State to care for poor consumptives, many of whom, sooner or later, become public charges, and it would be better to make them dependent, say, for eighteen months during the curable stage of the disease, at a probable cost of $300, and then restoring them to a condition in which they can care for themselves, than to allow them to become incurable.

DR. WILLIAM WARREN POTTER of Erie County then read a paper, entitled

THE ADVANTAGES OF STATE CONTROL IN MEDICINE, WITH RESULTS OBSERVED.

The first attempt to place the practice of medicine under State control was made by the Medical Faculty of the University of Buffalo in 1864, and nothing came of it. In 1883 the project was again revived, also in Buffalo, by the Medical Society of the County of Erie. A bill was then framed and placed in the hands of a committee which debated the question for two years before presenting it the Legislature It was not until June 5, 1890, that such a bill was passed, and the examiner appointed by the Board of Regents were not named until March 11, 1891. Practically four-years' work was lost by the Exemption Bill (passed at the instance of 900 medical students in the State) which provided that those who began the study of medicine previous to June 5, 1890, should be exempt from examination. At present the original bill is still in force, although many assaults have been made upon it by those antagonistic to laws governing the practice of medicine.

DR. R. C. M. PAGE of New York County read a paper on

ANEMIA

(which will appear in a later issue of THE MEDICAL NEWS).

DR. J. B. RANSOM of Clinton County read a paper on

EXPERT MEDICAL TESTIMONY.

Reference was made to a decision recently given in an Illinois court to the effect that a medical man must testify when called upon to do so, just as if he were an ordinary witness. This point the writer has contested three times in this State, refusing in each instance to answer a hypothetic question, and he considers the subject of regulating expert medical testimony one of the most important of the day. He suggested that medical experts be appointed by the Court, not more than three in number; that they be permitted access to all the papers in the case and to the defendant in the presence of the other experts, and be allowed to examine medical witnesses as to their knowledge. They should then set forth their opinion in writing, signed by all three, provided they agree on essential points, or should render individual reports in case of important disagreement. If counsel demands it, these experts may be sworn as witnesses to give testimony in the manner deemed proper by the Court. Such experts should be especially qualified for the purpose and examined for fitness by the Board of Regents, and they should be remunerated for their services, in amounts to be decided by the judge. Examination by the Board of Regents should be necessary before a man is given a certificate of qualification, and he should have practised medicine in this State not less than five years and be trained in the speciality in regard to which he expects to testify. The function of the expert witness is entirely different from that of the ordinary witness, and for that reason he should form part of the Court; his testimony should be judicial and not partisan. This plan would result in (1) the protection of the people; (2) the protection of the accused, and (3) the protection of the profession. No change in the present method, however, can be hoped for without the cooperation of the legal profession.

DISCUSSION.

DR. EVARTS M. MORRELL of New York County: I doubt if there is any subject which has excited more interest than the regulation of expert medical testimony. One of the reasons why so much ridicule has been heaped upon medical experts by the newspapers is because it often happens that a man is called to the witness stand to testify in a line of work with which he is not familiar, and in this way casts a slur upon the whole profession. Let me give a word of advice: Charge a good fee for expert medical testimony. Do not consent to testify for a small fee. The services of a physician are worth as much, and often more than those of a lawyer, and yet most people expect us to testify for a pittance.

DR. A. WALTER SUITER of Herkimer County: It has been my lot to have had some connection with the Committee on Legislation for a number of years past, and, therefore, I have become interested in this question which engages the attention, not alone of the medical profession, but of the legal profession as well. Being chairman of the committee which framed the bill, I endeavored to make some impression favorable to it when it was presented to the Reference Committee of the Legislature. I was at once met by the remark that the bill was not constitutional, in that it provided an expert for the prosecution and none for the defendant; that, if the defendant accepted the expert provided by the Court, he would not be able to call for any other, for he would then be placed in the position of attacking his own witness, which, of course, was ridiculous and compelled us to withdraw the bill. Various other bills have been prepared in other States, notably Illinois and Minnesota, providing that expert witnesses be appointed by the judge. These bills have all failed. I confess that I am very much discouraged. I do not think it is possible for any judge to make such an appointment without bias. I certainly think that experts should be properly qualified by examination and certificates from, the Board of Regents.

DR. LANDON CARTER GRAY of New York County: We really do not need to regulate expert testimony. What we do require is education of the lawyers. It is within the province of the lawyer to ascertain the qualifications which an expert should possess. It is owing to the lack of education on the part of members of the legal profession that incompetent men are allowed to testify. Selection of experts by the judge is a bad plan, for they know very little about physicians. Moreover, because of the political consideration with which he is burdened the judge is perhaps the worst man in the world to select an expert. It would be better if such a bill provided that the judge select an expert from a list prepared by the Board of Regents, but even this plan has serious disadvantages. I am sorry to say, but it is nevertheless a fact, that in some of our large cities there are a number of our professional brethren who are nothing more or less than blackmailers. They foist themselves into every case, and, if they are not selected by the lawyers, immediately go to the other side and without pay, perhaps, testify for that side in order to show the lawyers who did not employ them that they are powerful men.

DR. JOHN T. WHEELER of Columbia County read a paper on

THE COLD-WATER TREATMENT OF TYPHOID FEVER IN PRIVATE PRACTICE

(which will appear in a future issue of the MEDICAL NEWS).

DR. HENRY L. ELSNER of Onondaga County read a paper, entitled

THE VAGARIES AND WANDERINGS OF GALL-STONES, WITH CLINICAL REPORTS

(which will also appear in a future issue of the MEDICAL NEWS).

DR. EDWARD D. FISHER of New York County read a paper, entitled

PARALYSIS, PROGNOSIS, AND TREATMENT.

The author treated the subject under four divisions, *viz.*: (1) cerebral, (2) spinal, (3) peripheral, and (4) mus-

cular dystrophy. The first form is caused by meningeal or intracranial hemorrhage, thrombosis, tumors, injuries, etc. It is generally unilateral. The second form is due to disease of the anterior horns of the spinal cord, and is usually caused by inflammation, acute or chronic, hemorrhage, new growths, injuries, compression, spinal fracture, etc. Its principal characteristic is the wasting or atrophy of the muscles. The third variety is usually caused by constitutional dyscrasiæ, such as rheumatism or gout, lead poisoning, etc., and is associated with marked sensory symptoms. The fourth form, the cause of which is obscure, is apparently a developmental defect due to heredity. Prognosis is unfavorable in all varieties except the peripheral form. The treatment advised consisted of the application of electricity and massage.

EVENING SESSION.

The evening was devoted to a symposium illustrating the practical application of the X-ray in medicine and surgery. The exhibition was in charge of Dr. Arthur L. Fisk of New York County, and the program consisted of a display of X-ray apparatus, and an instructive and interesting illustration of its uses by Dr. Samuel Lloyd of New York County. Dr. Francis H. Williams of Boston followed with an interesting account of his application of the X-ray in medical cases. The author contended that in diseases of the heart, such as hypertrophy and dilatation, and in diseases of the lungs and pleura, more especially tuberculosis, emphysema, pleurisy, and empyema, more definite information can be obtained by the use of the X-ray than from percussion and auscultation. He recounted a case in which the progress of a tuberculous invasion of the lungs was accurately followed from its inception to the end. The use of the X-ray in surgery was entertainingly and attractively illustrated by stereopticon views of skiagrams of many complicated bone injuries by Dr. Fisk. Dr. William Hailes, Jr., of Albany County illustrated his clinical experiences with the X-ray and improved methods of microscopic projection.

SECOND DAY—JANUARY 26TH.

MORNING SESSION.

DR. E. F. BRUSH of Westchester County read a paper, entitled

THE IMPORTANCE OF THE HYGIENIC MANAGEMENT OF DAIRIES

(which will appear in a later issue of the MEDICAL NEWS,)

DR. N. H. HEATH of Erie County then read a paper on

THE MUNICIPAL CONTROL OF THE MILK-SUPPLY OF CITIES.

The officers for the ensuing year as reported by the nominating committee are as follows: President, Dr. John O. Roe of Rochester; vice-president, Dr. E. F. Brush of Mt. Vernon; secretary, Dr. F. C. Curtis of Albany; treasurer, Dr. C. H. Porter of Albany. The members of the various standing committees were generally retained, except those of the Committee on Prize Essays.

(To be continued.)

REVIEWS.

VITA MEDICA: Chapters of Medical Life and Work. By SIR BENJAMIN WARD RICHARDSON, M.D., LL.D., F.R.S. Longmans, Green & Co., 39 Paternoster Row, London, 1897.

THIS book will be welcomed by all who have followed the career or the teachings of its distinguished author, and they are many. The book does not profess to be an autobiography, but a reminiscence of the prominent events of the actor's life, in which not only are the serious affairs of life considered, but many interesting anecdotes are narrated. The book was evidently designed to be part of the Jubilee celebration of Queen Victoria's reign; indeed, it opens with a touching picture of the final leave-taking of the author's invalid mother on the day following the Queen's coronation, and was finished, as narrated in a note inserted by the author's son, "on November 18th, 1896, just before eight o'clock in the evening. At ten o'clock he was seized with the illness which ended fatally on Saturday morning, November 21st."

Sir Benjamin evidently took a serious view of life from his earliest cogitations, and a consciousness of the duties and responsibilities of a medical practitioner characterizes all that he writes. The volume makes very interesting and instructive reading.

THERAPEUTIC HINTS.

In Chronic Conjunctivitis, in addition to the correction of such possible causes as errors of refraction, a naso-pharyngitis, or an inflammation of the lachrymal sac, and attention to the condition of the general health, BERRY recommends for mild cases one of the following lotions:

℞	Ac. tannici	gr. ii–iv
	Sod. biboratis	ʒ i
	Glycerini	ʒ ii
	Aq. camphoræ	ʒ iv.

M. Sig. External use;

℞	Ichthyol	*m.* xx
	Aq. sambuci, Aq. dest. aa	ʒ ii.

M. Sig. External use.

To Remove Comedones.—Moisten a towel with the following lotion and apply to the affected areas, with friction, several times daily:

℞	Kaolini	℥ ii
	Glycerini	℥ iss
	Ac. acetici	ʒ i
	Ol. odorat.	q. s.

M. Sig. External use.

For Pharyngitis Sicca.—

℞	Ac. carbolici	ʒ i
	Tr. iodi	*m* v
	Tr. aloes	*m* vii
	Tr. opii	gtt. x
	Glycerini	ʒ i.

M. Sig. By means of an atomizer apply to the pharynx several times daily.

ORIGINAL ARTICLES.

ANEMIA.[1]

BY R. C. M. PAGE, M.D.,
OF NEW YORK;
PROFESSOR OF GENERAL MEDICINE AND DISEASES OF THE CHEST IN THE NEW YORK POLYCLINIC.

ANEMIA should be regarded as a condition secondary to some other affection rather than as a primary disease. The term itself is somewhat ambiguous, and is not infrequently used regardless of its real significance. For this reason we may assume at the outset that anemia signifies deficiency of red corpuscles or aglobulia. Then let us include under this head all such forms as hydremia, spanemia, and the like. When, however, there is increase of white corpuscles as well as deficiency of the red, then the condition is no longer one of simple anemia, but rather leukemia. The latter condition, as is well known, is always associated with hypertrophic enlargement of the spleen, in which there is an increase in the elements composing the normal splenic pulp. This disease is also called leucocythemia, and in all cases observed by me it has occurred in men from tropical or sub-tropical climates who had been subject to repeated attacks of intermittent fever.

In Hodgkin's disease, or lymphadenoma, the spleen is also enlarged, but this is due to two causes: First and most commonly, the increase in size of the spleen is caused by adventitious growths in its substance resembling mutton suet on section. In these cases there is simply anemia, but exceptionally the spleen is enlarged partly by hypertrophy of its normal elements and partly by the presence of adventitious growths. When this obtains we find not only anemia but also leukemia, as was observed in a case sent to me last year by Dr. W. N. Hubbard of the Out-Door Department of Bellevue Hospital. The disease is characterized not only by increase in the size of the spleen, but also by widespread enlargement of the lymphatic glands, usually beginning in the neck and extending into the axilla, groin, and elsewhere. I believe, also, clinically speaking, that this affection may be regarded as malignant.

The term chlorosis is indiscriminately used by most physicians and many authors to express the anemic condition, regardless of age or sex. I believe, however, with Dr. T. Gaillard Thomas, that it should be restricted to young girls, and only those who have not menstruated. It is true that such girls are usually anemic, but not necessarily so. Once establish the menstrual function and the chlorosis, or "green sickness," as it really signifies, disappears.

Pernicious anemia is a progressive disease first so-named by Biermer in 1871. Here we find simply diminution of red blood-corpuscles, many of which also become deformed without increase of the white, nor is there enlargement of the spleen. I have seen many more cases in the hospitals of Europe than in this country, and nearly always among women, especially women from twenty to forty years of age, and after repeated pregnancies. Chronic wasting diseases and certain uterine disorders may also cause the affection, but in some instances there appears to be no known cause. As in all cases of marked anemia there are the usual basic systolic heart murmurs and the venous hum heard over the neck. A valuable point in the diagnosis, as suggested by Dr. W. H. Thomson, is the presence of fever. The temperature varies from 100° to 101° F. The patient gradually declines, but death is generally due to some intercurrent disease, notably tuberculous nephritis, accompanied by marked dropsy. The pathology of pernicious anemia is not exactly known, but on account of capillary hemorrhages in the retina and other localities one is lead to suspect some disturbance of the sympathetic nervous system with consequent vasomotor irregularity. The disease is uniformly fatal, so that nothing more can be done than to attempt to prolong the patient's life by stimulants and highly nutritious food. Having very briefly alluded to leukemia, lymphadenomia, chlorosis, and pernicious anemia, I may now consider the chief subject of this paper, *viz.*, simple anemia.

As already said at the outset anemia may be regarded as a secondary condition rather than as a primary disease. It is, however, termed idiopathic anemia by some as well as simple or ordinary anemia. Perhaps insufficient food and overwork, especially when accompanied by bad hygienic surroundings, form the most frequent combination of circumstances which give rise to this affection. It is also due to excessive loss of blood from any cause, and frequently occurs during convalescence from severe sickness, as typhoid fever and the like—but there is one way in which

[1] Read at the Ninety-second Annual Meeting of the Medical Society of the State of New York, held at Albany, N. Y., January 25, 26, and 27, 1898.

anemia is brought about to which I wish especially to call attention, as first observed by Meinert of Dresden a few years ago. It is due to increased functional activity of the spleen from vasomotor disturbance of the nutrient vessels of that organ caused by prolapse of the stomach and bowels (gastroptosis, enteroptosis). We find the condition referred to chiefly among women with lax abdominal walls, such as those who have borne children, and those who, in following the prevailing fashion, wear clothing which presses down the stomach and bowels as well as the liver. We all know how common is what Strümpell calls the corset liver. In prolapse of the stomach the spleen is held firmly in position by the suspensory ligament. This allows traction on the splenic plexus formed by branches from the right semilunar ganglia of the sympathetic nervous system. These never accompany the splenic artery and its branches into the substance of the spleen. The traction on the splenic sympathetic nerve causes irritation, with consequent vasomotor disturbance of the nutrient vessels of the spleen, with increased activity of that organ. As an example of such irritation the increased heart-action in exophthalmic goiter may be given.

Accompanying the increased functional activity of the spleen there is generally some enlargement of this organ and also an increase in the number of white corpuscles of the blood without noticeable diminution of the red. Such a case could not, therefore, be called one of leukemia, but rather simple anemia. I have reason to believe that this condition of the spleen in simple anemia exists much more frequently than is generally supposed. After treating a patient for simple anemia for a length of time by ordinary methods I have been astonished at the lack of improvement. On examination, in such cases, I have invariably found slight enlargement of the spleen. These cases almost invariably occur among women. Instances of marked enlargement of the spleen are not referred to here, but I regard the spleen as sufficiently enlarged to require attention whenever it gives rise to marked dulness on percussion over the axillary line from the ninth to the eleventh ribs, with the patient in the erect position. In fact, it is a good rule when treating a patient for anemia to always begin by carefully examining the condition of the spleen.

Should improvement be slow and enlargement of the spleen suspected various remedies have been suggested with a view to lessening its size. To this end, while sufficient food of a highly nutritious order is indicated, excess is to be avoided, as well as a residence in a malarious locality. Ill-fitting dress should be remedied, and, as for drugs, I have found the internal administration of the iodid of potassium, with arsenic and an occasional positive dose of quinin, and, of course, the constant employment of some preparation of iron, to be most efficient. Combined with this the surface over the spleen should be rubbed every other night at bedtime with the iodid of mercury ointment (gr. ii to ʒ i). Red-oxid-of-mercury ointment may be used instead.

While administering iron the bowels, if necessary, should be regulated by some simple remedy, as the action of the iron will then be much more satisfactory. It is also well to remember that it is often a good rule to stop all such medication during menstruation.

THE COLD-WATER TREATMENT OF TYPHOID FEVER IN PRIVATE PRACTICE.[1]

By JOHN T. WHEELER, M.D.,
OF CHATHAM, N. Y.

THE experience of the profession with the Brand treatment of typhoid fever is a striking illustration of the fact that something more than scientific merit is needed in a therapeutic measure to secure its general adoption. The proof is ample that cold tubbing is the ideal treatment at the present state of knowledge, yet probably not one case in twenty in private practice is treated by this means to-day. Human nature, which has always to be reckoned with in our art, has rendered against it a verdict of "too heroic," and declares its preference for something perhaps more dangerous, but less distressing. Nevertheless, the Brand treatment is a magnificent achievement, and to it we owe, if not a rule of practice, the establishment of certain therapeutic principles which are the bed-rock of all sound antipyretic treatment.

Typhoid fever is a disease which varies so much in severity in different localities and different epidemics and is, moreover, so complex in character that a report by a single observer of a series of successful cases can never be conclusive as to the merits of a particular line of treatment. It so happens that I have all my life employed cold sponge-bathing in the treatment of typhoid fever, and, furthermore, I have never used any other treatment. My one hundred and twenty odd cases cover my entire professional experience of twenty-three years. The one locality in which I have resided is not favored as to mildness of climate, and the series of years includes several epidemics of decided severity, so that the general average of my cases would represent a fair average of the severity of the disease in question.

It may be a subject for wonderment that a man should practise medicine during the past quarter of a century

[1] Read at the Ninety-second Annual Meeting of the Medical Society of the State of New York, held at Albany, N. Y., January 25, 26, and 27, 1898.

and not in all that time be tempted to use some of the many remedies commonly employed in the treatment of typhoid fever. I adopted cold-water sponging in 1875, at a time when it was still regarded in my section as a daring innovation. It was a revelation to me then to begin the treatment of a delirious typhoid patient, sliding down in his bed, reeking with sweat, and with teeth covered with sordes, and, after a few days of bathing, see his expressionless face begin to show a sense of consciousness and comfort. I was successful in those early cases, and my success continued afterward, so that I never cared, and perhaps never dared, to try drug treatment. I have had but one fatal case. If, then, my uniform success is not fortuitous, it is entitled to be taken as fairly direct evidence as to the merit of cold sponging. Perhaps I might better stop here with the mere statement of the results of the treatment in my hands, since I lay no claim to originality in the technic of bathing nor in the discovery of any new principle. But there seems to be no one method of applying the milder forms of bathing, so that I may venture to emphasize one or two points which I have learned to regard as of special value, and to discuss also a point in general management which, more than any other, I think important.

We may consider typhoid fever, for the present purpose, as the result of the action of a toxin upon the living organism, manifesting itself by high temperature and its consequences, and by depression of the nervous system. Cold-water bathing does not, of course, destroy the toxin, but combats its effects in two ways: (1) by the lowering of temperature through the abstraction of heat, and (2) by the stimulation of the nerve-centers, thus maintaining functional activity and nutritive integrity by means of thermic and mechanical shock.

Mechanical shock or friction operates in two ways: (1) It excites the vasodilator nerves and so determines a free flow of blood to the periphery, thereby counteracting the danger of internal congestion which the application of cold water alone would produce, and also by bringing more heated blood to the surface to be cooled by the water, and (2) it stimulates the cutaneous nerves over a wide area, thereby reflexly stimulating the entire nervous system.

In making a greater use of friction than is commonly done, both for the good it can do by itself in stimulating the nerves and also in counteracting the circulatory disturbances due to prolonged use of the cold water, lies the point in which my practice may differ from that of many who employ the cold sponge. To have secured the same sum-total of heat abstraction and nerve stimulation by decreasing the intensity of the cold applications, and at the same time increasing their frequency and duration, is where, in common with those who employ cold sponging, I seem to have secured the advantages of cold tubbing without its drawbacks. To have become convinced of the supreme importance of bringing every available weapon in our armamentarium, balneopathic and otherwise, into prompt and energetic action at the onset of the disease is, to my mind, after the bath, the most influential factor in my success in the treatment of typhoid fever. If to this be added the fact that I am sure I have killed no one with veratrum viride or antipyrin, I have included, perhaps, all the features which distinguish my individual practice.

Briefly stated, my plan of bathing is this: I order that a bath be given every two hours during the day as soon as the diagnosis is made. The bath is continued from fifteen to forty-five minutes, according to the severity of the case. In a certain proportion of atypical cases with severe onset I use the bath almost continuously, hour after hour, and also in any case in which the response to the treatment is not satisfactory. I meet obstinacy of symptoms by persistency of treatment. At an early stage, with a heart yet strong, and with the free use of friction, this vigorous plan of treatment is possible.

I do not regard elevation of temperature as a criterion of the urgency of bathing, or depend upon the fall in temperature as a measure of hydrotherapeutic effect. The stimulation of the nervous system is the main thing to be accomplished.

The temperature of the bath should be a compromise in which the feelings of the patient, his strength, severity of symptoms, duration of bath, and amount of rubbing are determining factors; but oftenest it will be found that after a little the coldest water consistent with comfort is sufficient to meet the requirements. Weakened subjects with feeble peripheral circulation receive a preliminary rubbing in place of whisky or a hot drink. Friction, which brings blood to the surface and makes a patient feel warmer and causes him to accept his bath gratefully, does not of itself raise the temperature. Friction alone often quiets restlessness and puts the patient to sleep. Cases which by the tenth day are of mild type, however turbulent and threatening previously, are left without other treatment than good nursing. With two exceptions, I have regarded my aborted cases as instances of a mistaken diagnosis.

Hemorrhage from the bowels is a contraindication to bathing, a complicating pneumonia, not necessarily, and a bronchitis not at all. Every case must be considered individually, and much may be learned from and trusted to the observations of a nurse. She soon acquires a proper conception of the theory of the use of the bath, from discovering that it is her

work which keeps down the delirium, puts the patient to sleep, and cures the bronchitis; and, further, she learns to increase or relax her efforts with a definite and rational aim. Cases occur, however, which tax the vitality of subjects to the utmost and call for every kind of accessory support.

Next in importance to the bath itself is its early employment. The critical period of typhoid fever is not in the third or fourth week; it is in the first, and the battle is to be won or lost at this time.

Any one who plays whist knows that, although the interest centers toward the close on the fall of the last two or three tricks which win the hand, it is mainly the opening lead which determines the final issue, and in this fever it is equally true that that which culminates at the close is only a resultant of forces put in operation at the beginning. The daily damage from the typhoid toxin is no greater in any one day of the twenty-eight days of the fever than another, but the accumulated effect is more obvious toward the end. In fulminating cases the damage from the toxin is very great in the first week, yet I have come to regard such cases as ultimately mild, so certainly will persistent bathing break the power of the toxin to injure the organism.

The gastro-intestinal disorders of the first week are toxic. They are the first significant expression of lowered nerve tone. Calomel in small doses for a laxative effect, and strychnia and muriatic acid are helpful, but it is the sponging and rubbing which stop the vomiting, clear the tongue, and restore the appetite. To get the digestive apparatus in good order for the severe demands which are to be made upon it before it becomes functionally weakened is a matter of timely opportunity. I do not begin maximum feeding until assured on this point.

With bathing promptly begun during the first week I feel an almost positive assurance that the disease will be marked by a mild course. By this means the metabolic processes of the body are regulated so as to increase its resistance to the inroads of the disease; we have won Nature to our side in maintaining the strength and the general nutrition.

*THE VAGARIES AND WANDERINGS OF GALL-STONES, WITH CLINICAL REPORTS.**

By HENRY L. ELSNER, M.D.,
OF SYRACUSE, N. Y.;
PROFESSOR OF THE SCIENCE AND ART OF MEDICINE, AND CLINICAL MEDICINE IN THE SYRACUSE MEDICAL COLLEGE.

THE vagaries and wanderings of gall-stones, as exemplified in the cases which I am about to report, have seemed of sufficient interest to merit attention.

*Read at the Ninety-second Annual Meeting of the Medical Society of the State of New York, held at Albany, N. Y., January 25, 26, and 27, 1898.

The fact has been conclusively proven by clinical and *post-mortem* experiences that in a large number of cases in which gall-stones are ultimately found their presence was originally unsuspected. The diagnosis of cholelithiasis is often made with great difficulty, for there are so many conditions which simulate the presence of gall-stones that the diagnostician is frequently puzzled. The various manifestations of the symptom complex, associated with paroxysmal pain in the upper abdominal regions, many of the so-called gastralgias and enteralgias, often prove to be a typical example of cholelithiasis. The prompt acceptance of the truth of this statement promises, if acted upon by the diagnostician, to bring relief and cure to many; a conclusion justified by the brilliant results recently obtained in the field of hepatic and biliary surgery. This hope for the future is accentuated by the exhaustive studies and the growing literature on this subject to which I will refer later.

CASE I.—On March 20, 1895, Mrs. F., aged fifty-seven years, the mother of three children, consulted me on account of repeated acute pains which were referred to the upper abdominal regions. She was a woman who had always been obliged to work hard, and had been actively engaged in her household duties since her marriage. Careful inquiry into the history revealed the fact that she had suffered from repeated attacks of gall-stone colic. These were followed by great tenderness in the right hypochondriac region, and a moderate amount of jaundice. The diagnosis of cholelithiasis had never been made; hence, gall-stones had not been looked for in the stools. Between her attacks of gall-stone colic and after her recovery from the acute symptoms she suffered continuously from indigestion, both gastric and intestinal. On March 25, 1895, after a severe and characteristic attack, several small faceted calculi were found in a stool. The usual symptoms already mentioned followed this attack, but the patient appeared more tired and weaker than ever before. From March 25, 1895, until July 1st of the same year, with progressive emaciation and anorexia, she had repeated attacks of severe biliary pain, after none of which did careful search show the presence of gall-stones in the stools.

The tenderness over the right half of the epigastrium and right hypochondrium was constantly present. The patient became more emaciated, vomited a great deal, suffered from almost continuous pain in the region of the stomach and liver, and on July 5, 1895, a hard swelling about the size of a hazelnut was palpable near the border of the epigastric and right hypochondriac regions. This was tender and seemed to be slightly movable. Examination of the blood showed hemoglobin, fifty per cent.; red blood-corpuscles reduced to 3,000,000 per c.mm.; no increase in the number of, or change in, the white blood-corpuscles. The symptoms now seemed almost entirely referable to the stomach, and prompted

me to make an examination of the contents of this organ. After a test meal, on July 15, 1895, there was found complete absence of free hydrochloric acid, though pepsin and rennet were present, as was also a small quantity of lactic acid; there was a moderate amount of bile, and the total acidity was .025 per cent. Inflation of the stomach showed marked dilatation, with a tumor about the size of an ordinary egg occupying the normal position of the pylorus, and showing a considerable lateral movement during the inflation.

Taking the history into consideration, the increasing cachexia, the result of the chemic examination of the stomach contents, the dilated stomach found on inflation, the tumor occupying the normal position of the pylorus, its increase in size during the weeks preceding the final examination, the blood count, and low hemoglobin percentage, I was prompted to diagnose carcinoma of the pylorus associated with gall-stones. Repeated examination of the stomach contents failed to give results different from those first obtained. At no time did congo or tropeolin paper, or the Gunzburg test show the presence of free hydrochloric acid. The patient's suffering now became continuous, the tumor was at all times palpable, there was increasing splashing of the stomach contents, there was more or less peristaltic unrest, and the picture of carcinoma with constriction at the pylorus seemed complete. There was at no time more than a moderate amount of jaundice. The urine was of normal specific gravity, occasionally contained a trace of bile salts and pigment, but never albumin or sugar. An unfavorable prognosis was given, and, from day to day, the patient grew weaker and more wretched.

In this condition she continued until October 1, 1896, *a period of fifteen months after the recognition of the tumor, during which time the latter was always palpable.* At this time she was seized with violent pain which radiated throughout the upper half of the abdomen, and during my temporary absence from the city another physician was called to see her who partially relieved her by means of hypodermic injections of morphin. During the first week of October, 1896, symptoms of partial intestinal obstruction were manifested. There was considerable hiccough, increasing weakness of the pulse —which until the present time had been of good quality—while the tumor was no longer palpable. During my visit on October 8, 1896, I noticed a characteristic coiling of a portion of the intestine into a sausage-shaped mass in the upper part of the abdomen, stretching from the right to the left side, across the lower border of the epigastrium. This coiling continued for about sixty seconds, when it disappeared after an audible gurgling, with the relief of the acute pain. On the following day the symptoms were in no measure relieved, though the patient had passed some flatus *per rectum*, the tumor was not palpable, the upper abdominal regions were tympanitic, there was more or less vomiting of a dirty, green, and at times brown-colored, sour-smelling fluid, the coiling of the intestine had increased, and about four feet of intestine could be seen through the abdominal walls, sausage-shaped, tense before it collapsed after a characteristic gurgling in the upper part of the abdomen.

Deep palpation now showed the presence of a hard mass in front of the tense intestine, the size and shape of which corresponded exactly with that of the tumor originally found in the region of the pylorus. The nature of this tumor was no longer a matter of doubt, for I had concluded that we had an enormous gall-stone impacted in the gall-bladder simulating the symptoms of pyloric cancer. That this had been dislodged was no longer doubtful. The movable mass in its progress downward was giving rise to partial intestinal obstruction and increased coiling of the small intestine. On October 13, 1896, we were enabled to empty the colon by means of high rectal injections without making any impression upon the symptoms referable to the small intestine. The strength of the patient continued about the same, the temperature ranging between 97.9° F. and normal; the tongue throughout was moist and stained by the vomited matter. On October 14, 1896, the coiling seemed to involve the entire length of the small intestine which could be seen, as before, through the abdominal walls distinctly sausage-shaped, and the different coils could be moved upon each other. The increase of coiling seemed to justify a delay in instituting surgical interference, I concluded that obstruction was not complete, and that the obstructing mass was movable, as shown by the increased length of the intestine involved from day to day. I felt that if the strength of the patient would permit we might wait until the offender was safely passed into the large intestine by Nature's effort.

On the morning of October 16, 1896, with Dr. Coe of Syracuse, the patient was visited for the purpose of determining a method of hastening the passage of the mass. On entering the room our patient received us cheerfully. She informed us of the fact that after a night of considerable suffering from rectal tenesmus, without coiling of the small intestine, she had passed an enormous stony mass, which she had left in the vessel, where Dr. Coe and I found it. It proved to be a gall-stone, composed mainly of cholesterin. Its circumference was 13 cm. (5½ inches), its length 7.5 cm. (3 inches), and its weight was 368 grains. There were no further symptoms referable to the abdominal organs, the patient gained strength and flesh, and after a few weeks she resumed her household duties. The stomach, while still somewhat dilated, performed its functions satisfactorily, and to all appearances the patient was fully restored to health.

About eleven months after the passage of this enormous gall-stone and during my absence from the city, my assistant, Dr. Kieffer, attended the patient for what was considered an acute indigestion. There were no pains characteristic of gall-stone colic. Four days after this visit the patient sent a gall-stone to my office which she had passed after considerable rectal spasm. It weighed 240 grains, was 5 cm. (2

inches) long, and 7.5 cm. (3 inches) in circumference. Since the passage of this last gall-stone the patient has remained well.

From a diagnostic, as well as from a pathologic standpoint, this case is full of interest. The complete clinical picture of cancer of the pylorus, coupled with cholelithiasis was presented. No other diagnosis seemed justified when we considered the previous history, the repeated attacks of gall-stone colic, the final tumor persisting for months, with gastrectasia, the characteristic displacement of the mass to the right and its upward movement on inflation of the stomach, and finally, the results of the analysis of the stomach-contents, with the emaciation and cachexia. With these conditions present, the gall-stone disease was readily considered to be of secondary importance. The irregular forms of gall-stones, as Naunyn has forcibly demonstrated, by prolonged incarceration may give rise to a variety of pathologic complications, the most serious of which are attributable to added infection or ulcerative changes. In the case reported the enormous gall-stone which finally gave rise to partial intestinal obstruction, had filled the gall-bladder, which organ, as the result of protective and adhesive inflammation, became adherent to the duodenum. The pylorus was sufficiently distorted by traction and thickening to suffer ultimate constriction with consecutive gastrectasia. After fifteen months of retention in its capsules, the offender escaped by an ulcerative process through a fistulous opening into the duodenum, the free peritoneum being well protected. In its descent downward the stone was arrested at various points, causing obstruction with increasing intestinal coiling, and all of the other symptoms mentioned. The final unique feature of the case was the passage of the stone eleven months after the disappearance of the tumor, without the usual painful symptoms. Undoubtedly this stone originally formed a part of the misleading tumor, but it had found during its detention—and after the escape of the first large stone—a suitable resting-place in a diverticulum of the adherent gall-bladder, a condition pictured by Riedel.[1] Finally the stone escaped through the patent fistula into the duodenum. The fact that the last stone did not give rise to symptoms is by no means surprising, for incarcerated stones have frequently been found without having been suspected in spite of the fact that great local mischief had been done. Many of these unsuspected cases are associated with malignant disease. The writer has several times found innumerable concretions in the smallest branches of the hepatic ducts without a single symptom referable to the liver.

It will be profitable in connection with this case to consider three points: (1) The simulation of pyloric carcinoma. (2) The ulcerative process causing the gall-bladder-duodenal-fistula. (3) The final intestinal obstruction (incomplete).

1. The simulation of pyloric carcinoma which continued in this case during fifteen months is not entirely without parallel. Simulation was made easy by the presence of the tumor, the ultimate production of stenosis of the pylorus, and dilatation of the stomach. Eminent clinicians have been mislead in similar instances.

Pepper[2] reports a case in which there was a gall-stone of unusual dimensions which simulated scirrhus of the pylorus with all of the symptoms of cancer of the stomach, including persistent vomiting and great irritability of the stomach. The patient died three weeks after coming to the notice of the physician, some six months after the commencement of the illness. "The tumor felt during life, in the pyloric region, proved to be a large gall-stone completely filling the bladder and molded to its shape. The gall-bladder itself, however, was perfectly healthy, as was also the liver and its ducts. The surface of the stone was unusually smooth, of a light yellowish color; it weighed a little more than half an ounce, and measured two inches in its greatest circumference, and in length it was two and one-half inches. Portions of the small intestine were agglutinated together; their walls were adherent in several places, and they connected with each other through ulcerative openings. The stomach was perfectly healthy." Other parallel cases are reported by Miles,[3] Fiedler,[4] Ross,[5] Hale White,[6] and Ogle.[7]

In all of these cases, as in the case reported by the writer, there was gastrectasia and a palpable tumor. In the case reported by Miles, there were evidences of fermentation of the stomach contents. In the cases of Fiedler and Ross there was vomiting of blood. In all of these cases the authors mentioned made during life a positive diagnosis of cancer of the pylorus. Naunyn[8] reports a case which he observed in Königsberg, in which a tumor persisted during seven months in the region of the pylorus. At first it grew rapidly, then suddenly disappeared. While it was palpable there was persistent vomiting. After one year there was recurrence of the tumor, recurrence of vomiting, persistent pain in the right hypochondrium, gastrectasia, fermentation, increasing cachexia, and finally coma and death. At the *post-mortem* an enormous gall-stone was found, and it entirely filled the gall-bladder; there was ulceration of the adherent duodenum, the gall-bladder itself was ulcerated in spots; besides the communication with the duodenum there was a fistula leading from the gall-bladder into the colon.

Fiedler's case was that of a woman sixty-six years

of age, who had repeated attacks of so-called gastralgia with chills, beginning one year before coming under observation. She finally developed gastrectasia, hematemesis, pyloric tumor, disappearance of the tumor, followed by intestinal obstruction persisting during six days, and the stone finally passed the rectum; its weight was 12 grams (180 grains).

Naunyn[9] reports Schreiber's case in which Mikulicz operated for pyloric stenosis which was supposed to have been caused by an ulcer. He found a large gall-stone forming the base of a pyloric ulcer, which latter he removed. The patient was cured.

Similar conditions have been found *post-mortem* by the writer, demonstrating the fact that a gall-stone may cause perforation, remain in its original position for some time before migrating, or it may not migrate at all.

2. The aberrance of large gall-stones through fistulous canals into the intestine occurs oftener than has been suspected. If careful examinations were made, many cases of doubtful hematemesis and intestinal hemorrhage would be found to be due to perforation from this cause. The profession has only recently awakened to an appreciation of this fact. It is interesting to note that, with the exception of the one case in which a gall-stone perforated the gall-bladder and passed into the jejunum, reported by Bartholin[10] in 1654, no instance of ulceration of a stone from the gall-bladder into any of the abdominal organs was reported until 1770, when Beaussier[11] reported the first case of a gall-stone ulcerating its way into the stomach. In 1775, J. G. Walter[12] reported the first gall-bladder-colon-fistula, while in 1783, Blumenbach[13] made the first report of a gall-bladder-duodenal-fistula. Courvoisier[14] calls attention to the fact that at the end of the Eighteenth Century there were but nine cases of gall-bladder-intestinal-fistula recorded, while three times as many cases of intestinal obstruction due to gall-stone had been reported. The latter fact is proof positive of the unsuspected frequency of associated inflammatory and ulcerative processes in many of these cases.

Of 499 perforations due to gall-stones, 83 opened into the duodenum, and 39 into the colon (Courvoisier[15]). In compiling the cases of cholelithiasis, I found that 421 were examined *post-mortem* at Basel from 1872 to 1888, in which there were 19 perforations or 4.7 per cent. In adding the cases of cholelithiasis observed by Roth, Courvoisier, and Schloth, 166, 255, and 343 respectively, a total of 764 cases, I found that perforation into some part of the intestinal tract occurred in 25 cases. The proportion of colon to duodenal fistulæ, as near as I can determine, is practically 1 to 2.5.

3. In connection with Case I. the occurrence of complete or partial intestinal obstruction deserves more than passing notice. With the disappearance of the original tumor, and the appearance of intestinal distention and the gurgling followed by immediate collapse of the tube, came the suspicion that the offender was a gall-stone of considerable size. The literature relating to intestinal obstruction due to gall-stones is by no means meager, and the possibility of its occurrence must not be forgotten. In fact, we must conclude that the occurrence of intestinal obstruction, after the passage of gall-stones from the gall-bladder into the intestine, is surprisingly frequent, owing to the large size of these stones. Thus, Courvoisier[16] reports ileus in twenty-eight of seventy-three cases, or 38.3 per cent.

We are frequently misled in our diagnosis because of the fact that gall-stones find their way into the intestinal tract through fistulous openings without producing symptoms until the sudden occurrence of obstruction. The differential diagnosis of the cause of the obstruction in this class of cases cannot possibly be made. Mayo Robson[17] reports cases of acute intestinal obstruction from gall-stones, in some of which recovery followed operation, in others the stones, after a number of days, were passed *per rectum*. In one case reported by Gray[18] obstruction continued twelve days before the stone was dislodged. Craigie[19] reports a case in which intestinal obstruction continued nine days, at the end of which time the stone was passed and the patient recovered.

The prognosis is much more serious when ileus follows gall-bladder-duodenal-fistulæ then when the opening is into the colon. Of thirty fatal cases, twenty-eight were due to gall-bladder-duodenal-fistula, and only two to gall-bladder-colon-perforation (Naunyn[20]). If a gall-stone finds its way directly into the duodenum through the common duct there is but little danger of intestinal obstruction. The rarity of ulceration of stones large enough to cause intestinal obstruction through the choledochus walls is emphasized by Courvoisier[21]. He found in thirty-six cases in which large stones entered the intestine and in which *post-mortems* had been made, that in three the stones had escaped through the common duct.

The expectant treatment, in the writer's case, seemed justified because it was reasonably certain that a gall-stone was present, and that it was slowly moving along. Robson[22] says, "If it were possible to be certain that a gall-stone is the cause of the block, the expectant form of treatment would be fully justified, since the probability, arguing from published cases, is that the gall-stone will eventually pass." The same author suggests that in those cases offering "diagnostic difficulties" the surgeon is ac-

cepting "great responsibility in waiting for Nature's cure." Naunyn[23] makes the statement, after considering the results of thirteen operations for ileus due to gall-stones—of which number only one resulted in recovery—that laparotomy is not to be recommended, and in over fifty per cent. of the cases recovery results without operation; that frequently the condition yields after from seven to nine days of obstruction, and as operators will always be encouraged by these facts, they will rarely operate early, hence they will find, with late operations, necrosis of the intestinal wall and circumscribed peritonitis. Langenbuch[24] takes a more extreme view of this question. He makes the unqualified statement that "gall-stone obstruction is a surgical disease, the treatment of which is to be entrusted to the physician only during a very short period."

Case II.—On September 12, 1897, I saw Miss W., aged twenty years, a student, in consultation with Drs. Easton and Kellogg of Syracuse. Her family history was negative. Prior to January, 1897, she had been in good health. While in Chicago shortly after January 1, 1897, she was taken with fever and evidences of tonsillitis, and finally more or less pain in the upper abdominal regions, marked gastroduodenal disturbance, rapid pulse, and, after a few days, repeated chills, which observed a periodicity, recurring at intervals of from twelve to twenty-four hours, without (at this time) noticeable jaundice. The physician in attendance during her stay in Chicago considered her trouble to be of malarial origin, and treated her accordingly. She remained in bed five weeks, had not then convalesced completely, but continued to complain of vague symptoms, malaise, and a generally reduced condition, when, in March, 1897, she was suddenly seized with severe lancinating pains in the right hypochondrium, which continued acute during two hours. Her symptoms of gastrohepatic disturbance now became continuous, and she had had at intervals of a few weeks, when Drs. Easton and Kellogg saw her, what to them seemed characteristic attacks of gall-stone colic.

On August 9, 1897, she became jaundiced. Dr. Easton attended the patient in Syracuse. She had with each attack of colic more or less elevation of temperature, usually between 100° and 101° F. A sharp rise of temperature, averaging 103° F., followed the more acute exacerbations of what had now become a chronic condition. Jaundice persisted, and became more intense with each paroxysm of pain. Her temperature was at no time normal, being usually slightly elevated. Between the attacks her pulse was at all times alarmingly rapid, without encouraging arterial tone. The urine had been examined and found bile-tinged, without albumin, and negative in other respects.

I found the patient in a typhoid condition. The tongue was characteristic; pulse varied in frequency from 110 to 120; at one time during the consultation it fell to 100 per minute. Temperature, 100° F. There was intense jaundice, with all evidences (subjective and objective) of profound infection associated with disease of the gall-bladder and bile-ducts. The intestines were distended with gas. The most acute suffering on pressure was located in the region of the gall-bladder.

Physical Examination.—There was nothing noteworthy in the thorax. The abdomen was tympanitic and tender to pressure. Careful examination revealed a mass corresponding in size to a goose-egg, which gave fluctuation on deep pressure. This tumor moved up and down with respiration. The liver dulness was slightly increased. The spleen was somewhat enlarged.

A diagnosis of infectious cholecystitis, cholangitis, empyema of the gall-bladder, and associated gall-stone was made. We concluded that in all probability there was occlusion of the common duct. Immediate operation was recommended. Dr. Easton took the patient to New York, where on September 20, 1897, Dr. Lange operated, opening the gall-bladder, which was found filled with pus. A gall-stone the size of a beach-nut was found in the gall-bladder. The cystic duct was occluded. The common duct was palpated, found hard, thickened, but no stone could be felt in it. It was not disturbed. Following this operation there was slight improvement. Whatever discharge finally escaped through the wound proved to be the secretion of the gall-bladder only. The temperature was lowered, there was less jaundice, though this was not materially changed.

About October 1, 1897, the patient had a chill, after severe biliary colic requiring morphia for its relief. The pulse again became rapid, fever high, and the icterus decidedly deepened. The stools continued putty-colored. The patient's condition warranted the conclusion that the common duct was still obstructed, and that there was either hardened mucus and pus, or gall-stones which had been forced to the obstruction, giving rise to the characteristic pain of biliary colic. The deep jaundice and other increasing positive evidences of obstruction of the common duct prompted Dr. Lange to undertake a second operation on October 6, 1897. On opening the common duct no stone was found in spite of careful search, but a cicatricial contraction was felt at the point of entrance into the duodenum. A new opening was made into the duodenum, and an anastomosis was then established between the common duct and the intestine. Dr. Lange reported everything progressing favorably for five days, when, after the removal of the tampon, the suture line leaked, and for about one week bile and duodenal contents escaped through the wound. The general condition of the patient suffered materially. Finally, the skilful surgeon by means of persistent posture on the left side, and an improvised tamponade succeeded in healing the wound. There were no further symptoms of obstruction. The discharge once checked, the jaundice disappeared, and recovery was uninterrupted. A fistula opening into the gall-bladder has

remained, but the discharge from this is but slight, nothing more than a trace of mucus daily, and causing no inconvenience. This can be overcome later if indications demand it.

In the hands of a less experienced surgeon, this young life would in all probability have been lost. The case is as interesting in its pathologic as in its surgical aspect. The history strengthens the more recent views which attribute to infection an important rôle in the causation of pathologic changes within the bile passages, and in the production of gall-stones. The primary illness associated with tonsillitis in January, 1897, was a far-reaching infection; this spread from the intestine, where there may have been a duodenal ulcer in the region of the papilla, to the bile passages and gall-bladder, causing cholangitis, cholecystitis, and gall-stone formation, with empyema of the gall-bladder and consecutive occlusion of the cystic and common ducts, the latter due to deep ulcerative or inflammatory changes. The enlargement of the spleen found at the consultation on September 12, 1897, strengthens these conclusions.

Dr. Lange wrote: "I was also under the impression that the pancreatic duct was dilated, and formed, with the end of the common duct, a rather large cavity, into which I was able to pass my finger behind the posterior wall of the duodenum."

The great interest in this case is centered in the unique obstruction of both the common and cystic ducts, as the result of violent infectious cholecystitis and cholangitis. Such cases are exceedingly rare. I have thoroughly searched the authorities on this subject at my command, and find no cases which seem to correspond exactly with the one here reported. In the large proportion of choledochus strictures reported the duct was much dilated, resembling at times the gall-bladder. Langenbuch[25] reports four cases of common-duct stricture in which choledochostomy was performed. In each of these there was enormous cystic dilatation of the common duct, which in each case had been opened and drained; the respective operators supposed that they were dealing with a distended gall-bladder, never suspecting the distension of the common duct. In two of these cases the autopsies proved the fallacy of the operators' conclusions (Helferich and Ahlfeld[26]).

In the case of Levy[27] the duct was bent upon itself, distended, and mistaken for the gall-bladder. In the fourth case (Quenu[28]) a large abscess was opened which was not connected with the gall-bladder, but was, according to Terrier, in all probability connected with the common duct. Yörsen[29], during a laparotomy, found a swelling the size of an apple, which, owing to its position, he supposed to be the gall-bladder. He opened the mass, after stitching it to the abdominal walls, and gave exit to foul-smelling pus and gall-stones. The patient died the following day. It was demonstrated that the common duct had been fastened to the parietal peritoneum—the gall-bladder was not involved. Kocher[30] was the first to avail himself of the original suggestion of Langenbuch. The latter had called attention to the possibility of establishing an anastomosis between the common duct and the duodenum, the operation which Lange performed in the case reported.

Kocher's case was one in which a gall-stone was impacted in the common duct. He was fearful that lithotrity might fail; he therefore introduced his sutures into the duodenum and common duct with the idea of ultimately uniting these if necessary. The stone yielded and the anastomosis was not made. Besides this case, in which choledocho-duodenostomy had been performed, I find one reported by Riedel.[31] In this case the operation was performed for impacted stone, which the operator could not reach in the common duct. He made an anastomosis between the common duct and the duodenum. The stitches gave way, owing to the thin choledochus wall. The patient died of peritonitis. Sprengel[32] reports recovery in a case in which he first did a laparotomy and attempted to push a stone impacted in the common duct into the duodenum. In this he failed, and closed the abdomen. Three weeks after this operation he made a second attempt, and completed the operation with a choledocho-duodenostomy.

Terrier[33] and Kocher[34] each report a case in which the anastomosis became necessary in complicated constriction from gall-stone, and in which the patients made a happy recovery. Czerny[35] reports a case in which he united an enormously dilated and constricted common duct, by means of the Murphy button, with the duodenum. The case is supposed to have terminated favorably.

Cases in which there has been obstruction to the outflow of bile, from the choledochus into the duodenum, and in which the simpler operation of chollecysto-enterostomy has been successfully accomplished, do not concern us in considering the case reported. Anastomosis between the gall-bladder and duodenum is to be preferred, provided the former will serve as a canal to return the bile from the common duct above the constriction to the intestine. It has occasionally been found impossible to establish the communication with the duodenum, hence the colon has been made the receptacle of the diverted bile. The suspicion of ulcer of the duodenum, expressed in considering the pathology of the case reported, is justified by a statement made by Langen-

buch,[36] in which he mentions the possibility of cicatricial contraction of the common duct following duodenal ulcer; but he fails to mention a case. Courvoisier[37] has collected sixty-two cases of obliteration of the choledochus. Of this number seventeen were congenital. The majority of these were due to fetal inflammation; in all probability most of these were of specific origin. Cholelithiasis was found to be the more frequent cause of constriction of the common duct after birth, and was found in twenty-three cases. In one case reported by Archambault,[38] there was obliteration of the common duct due to a typhoid process propagated from the intestine. A case of Richard's[39] is reported in which there was a benign stricture of the pylorus which involved the common duct in the cicatricial contraction. Musser and Keen[40] report a case of common-duct obliteration due to chronic enteritis, and make mention of the "closure of the ducts" by the "healing of an ulcer in the duct or at the duodenal orifice." Courvoisier's list contains three cases[41], [42], [43], in which traumatism was supposed to have caused obliteration of the choledochus. In the remaining cases reported by Courvoisier, the histories do not justify positive conclusions as to the origin of the obliteration of the duct, but the compiler adds, "the thought which one must always entertain in connection with these cases is that irritation from gall-stone descent is the more probable cause, though this cannot be proven."

Case III.—In this case a man, aged about fifty-five years, was seen in consultation with Dr. George R. Kinne, and the patient presented all of the symptoms of grave abdominal disease. There were no evidences of stenosis or intestinal obstruction, but all of the usual symptoms of malignant disease of the mesenteric glands, with more or less pancreatic indigestion. There were no symptoms referable to the gall-bladder; the patient had never had gall-stone colic. Emaciation was progressive and after the lapse of six months he died of asthenia. There was a suspicious dulness in the upper part of the epigastrium.

The *post-mortem* revealed the fact that a gall-stone had quietly burrowed its way from the cystic duct into the retroperitoneal space, and had found a resting place in a dense connective tissue capsule back of the pancreas. There were evidences (in uneven dilatations of the fistulous tract) of incarceration at several points during the progress of the stone to its final resting place.*

Case IV.—The patient was a man, aged sixty years, who came to Syracuse from the lumber regions of Michigan. He had had repeated attacks of vague abdominal pains, and had often suffered from intermittent malarial fever. On one occasion, about two years before he came to Syracuse, he had a severe attack of what, in the light of subsequent developments, must be considered gall-stone colic. He seemed to recover from the acute attack, but was never free from pain in the right lumbar region. After a few months he developed a train of symptoms referable to the genito-urinary organs, particularly the right kidney. At one time he claims to have had free hematuria. Subsequently, the color of his urine became dirty brown and flaky. Emaciation was progressive. He finally became cachectic, and when I saw him was almost moribund. About two weeks after my first visit he passed a small calculus, *per urethram*, which fell into the vessel and was not saved. The urine contained bile, blood, pus, and albumin. He died four weeks after his arrival in Syracuse.

The *post-mortem* disclosed a fistulous tract leading from the gall-bladder into an abscess the size of an orange, and from this to the pelvis of the right kidney, in which we found an enormous cholesterin gall-stone. The gall-bladder wall was thickened and contained three good sized gall-stones. The abscess was surrounded by a dense mass of connective tissue. The kidney tissue was infiltrated and presented a characteristic yellowish-brown appearance.

Courvoisier[44] reports seven cases of urinary fistulæ associated with gall-stones; six of these were found in women. In one of these cases, reported by Pelletan and Barraud,[45] 200 stones passed the urethra within eight days. In this case the last stone became caught in the urethra, but was easily pushed on from the vagina. The patient recovered. An abstract of the histories of these cases makes very interesting reading and can be found in Langenbuch's[46] recently published work.

Experience has convinced me that in many cases cholelithiasis, with or without colic, is early associated with localized peritonitis. This may, in some instances, be a fortunate occurrence for the patient where ulceration finally takes place, but in a number of cases consecutive adhesions with distortion and displacement of the gall-bladder and adherent intestine have caused insuperable obstacles to the performance of life-saving surgical operations, and have given rise to annoying symptoms.

Case V.—Patient, female, aged thirty years, seen in consultation on June 21, 1895, with the late Dr. Magee. She had all of the symptoms of impaction of a gall-stone in the common duct, with associated localized peritonitis and infection. In spite of the fact that both Dr. Magee and I insisted upon immediate operation, other consultants doubting our diagnosis the operation was delayed until the woman was practically moribund. Dr. Magee opened the abdomen, found dense adhesion of the gall-bladder to the duodenum. The parts were drawn backward and downward. The common duct could be distinctly felt filled with enormous gall-stones, but surgical relief was made impossible by the depth of

* Only three cases of retroperitoneal perforation were found in the collection reported by Courvoisier.

the parts and their changed anatomic relations. The patient died. The *post-mortem* showed three stones closely packed in the common duct, the surface of which was ulcerated and the duct itself enormously distended, besides the conditions mentioned.

In many cases pain in the region of the gall-bladder, after the passage of gall-stones, becomes persistent. This symptom is due to adhesions of the gall-bladder to the surrounding parts and to traction. Mayo Robson[47] reports cases of this kind in which he operated, overcoming adhesions, to the great relief of his patient. These operations were undertaken for the removal of suspected gall-stones. My list of cases includes a considerable number in which gall-stones found exit through the abdominal wall. The point of perforation was usually in the neighborhood of the umbilicus. These cases present no unique features, and I will not dilate upon them. One of these, however, is interesting from the fact that the patient is now seventy-seven years of age, and that during the past twenty years she has passed innumerable biliary calculi through an opening in the abdominal wall, which closes, as a rule, within a few weeks after the passage of a stone. Her general health does not seem to suffer in consequence of these occurrences.

CASE VI.—Patient, Mrs. H., aged fifty-six years, was first seen in consultation with Dr. Doust. In this case there was a history of gall-stone disease, with repeated attacks of colic, dating back twenty-five years. When I saw her on October 19, 1897, she was deeply jaundiced and had all of the symptoms of gall-stone impaction in the common duct. There were also evidences of an enlarged gall-bladder and liver.

During the course of a few weeks the patient passed a large number of small gall-stones, without relief of her symptoms. On December 9, 1897, I again saw her in consultation with Drs. Doust and Breese, when a fistulous tract was found at a point about two inches below the free border of the ribs on a line drawn from the right sternoclavicular articulation. Within a few days after this visit Dr. Breese examined the patient under ether. He opened the sinus, through which yellowish pus had escaped, but failed to find an opening from this into the gall-bladder.

On January 14, 1898, Dr. Breese again opened the abdomen. He found the gall-bladder everywhere adherent and hard. Pressure on the surface of the gall-bladder gave a peculiar grating. The anterior wall was converted into dense cicatricial tissue and was continuous with the liver, from which it could not be separated. The cystic duct was obliterated and converted into a dense mass of infiltrated tissue. The pancreas was hard. The adhesions were so dense and the changes so far reaching that the surgeon could see no way of overcoming the obstruction; hence, the abdomen was closed. At the *post-mortem* the gall-bladder was found to contain 601 small pyramidal hard white stones. The induration of the common and cystic ducts had an appearance suspicious of carcinoma. There were a few enlarged glands to be seen back of the gall-bladder. The mural abscess was probably due to the escape of one of the small stones, after which the gall-bladder closed and detached itself from the parietal peritoneum. The hepatic duct was obliterated at its junction with the cystic. The ducts above the obliteration were enormously dilated and were filled with bile.

My clinical experiences have demonstrated the fact that gall-stone colic is not entirely without danger from sudden heart failure. In elderly people the association of gall-stone disease with myocardial degeneration is not at all uncommon. In some of these cases I have also observed associated diabetes. In a case seen a number of years ago the patient, who had had repeated attacks of gall-stone colic, was suddenly seized during one of these with violent precordial pain, and immediately expired. The *post-mortem* examination showed well-marked myocardial degeneration, dilatation of the heart, with partial rupture in the anterior wall of the left ventricle. A gall-stone the size of an ordinary marble was found impacted in the cystic duct. In a number of my cases of persistent jaundice due to long-continued gall-stone impaction, alarming brain symptoms developed. In one of these an old man became violently insane. The insanity yielded with the relief of the obstruction and the disappearance of the jaundice. A similar case was recently seen in consultation with Dr. Jacobson, in which prolonged cholemia due to obstruction of the common duct caused confusional insanity.

Gall-bladder infection from the presence of the bacillus typhosus, also the involvement of the bile ducts in a similar process, or suppurative cholangitis, with and without gall-stone formation, have been observed by the writer, but these cases cannot be considered at this time. An attack of gall-stone colic masked the early diagnosis of a case of typhoid fever seen with Dr. Joy at Casenovia a few months ago. A coachman, who had previously suffered from gall-stones, while driving was suddenly seized with high fever and the usual pains of an ordinary bilious colic. He had been feeling badly for several days before the attack. Great tenderness over the region of the gall-bladder persisted, with slight jaundice and evidences of localized peritonitis. The high fever was entirely out of proportion to the extent of the local peritonitis. We found, as the disease progressed and time was given for diagnosis, that he had typhoid complicated with cholelithiasis. The patient recovered.

Only once have I found *post-mortem* the ball-valve gall-stone in the common duct in the diverticulum

of Vater, a condition which has been so thoroughly described by Osler[48]. I have seen several recoveries after recurring symptoms of partial obstruction of the common duct, with occasional marked exacerbation and deepening of jaundice. These cases were usually accompanied with the intermittent hepatic fever described by Charcot, which led me to believe that I was dealing with a ball-valve gall-stone in the common duct.

Since the appearance of Courvoisier's, Naunyn's, and Mayo Robson's elaborate monographs, Riedel's work in 1892, in which his statistics showed a successful issue in ninety per cent. of gall-stone operations, the monumental work of Langenbuch, recently published in the *Deutsche Chirurgie*, and the convincing paper read by Lange[49] of New York at Johns Hopkins', the duty of the diagnostician has been made plain. The symptoms of all cases of cholelithiasis demand correct interpretation at the earliest possible moment. I have attempted to demonstrate, both by clinical and pathologic data, that processes which are protective may at the same time seriously interfere with the surgeon's results. I feel justified in concluding that the persistence of gall-stone symptoms demand the same concerted action of physician and surgeon that has so promptly succeeded in reducing the mortality from appendicitis. The surgeon will always require the physician's knowledge of pathology in these cases and possibly some of his conservatism to guide him, but together, they will ultimately find themselves breaking loose from extreme views to meet on vantage ground where deliberate judgment and sound reasoning will prevail.

CLINICAL MEMORANDUM.

A PERSONAL EXPERIENCE IN RENAL SURGERY.

BY ROBERT F. WEIR, M.D.,
OF NEW YORK;
PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, AND SURGEON TO THE NEW YORK HOSPITAL;
WITH THE COLLABORATION OF
EDWARD M. FOOTE, M.D.,
OF NEW YORK;
SURGEON TO THE RANDALL'S ISLAND HOSPITALS.

(Continued from page 146.)

TUBERCULOSIS.

THE possibility of an early diagnosis of this form of renal infection has been much increased during the past few years, and especially by the use of the cystoscope. This instrument will some day perhaps settle the much-disputed question as to whether the kidney affection is primary or secondary to tuberculosis of the bladder, prostate, etc. It was formerly the almost universal opinion, from clinical data alone, that the infection traveled upward through the ureter. Donnadieu,[1] in a comprehensive article, showed some time ago the difficulty of deciding the question at an autopsy, when the lesions found in both kidney and bladder are usually caseous, so that it is impracticable to speak of their relative age. He quotes Guyon as saying he had observed but one case of uncomplicated renal tuberculosis. Since that time, however,

[1] *Arch. clin. de Bordeaux*, November, 1892.

numerous instances of undoubted primary renal tuberculosis have been reported, among them being an interesting one of Thorel's.[1]

More commonly, however, the kidney is secondarily infected from a previously existing pulmonary tuberculosis. This occurs in from thirty-four per cent. (Brown) to fifty per cent. (Morris, Steinthal) of the cases. The miliary form of infection presents in about one-third of the instances, and then usually invades, according to many writers, both kidneys. This, however, I am inclined to doubt. In the other two-thirds the involvement was found more advanced; that is to say, it is presented in the form of caseous deposits, and, what is of surgical importance, about one-half of these lesions were confined to one kidney. In cases of all kinds of a somewhat chronic form which admit and demand surgical attention, and which have arisen in distant tuberculous foci or in other parts of the genito-urinary tract, *e.g.*, the testis, prostate, and bladder, it has been demonstrated that the renal lesions are one-sided in about one-half of the cases (Steinthal, twelve out of twenty-four cases).

The localization of lesions in both kidneys is more apt, according to Dickinson, to be found in children under twelve years of age, for in twenty-eight cases reported by him it occurred nineteen times in both kidneys and nine times in a single kidney. In persons over twelve years of age, however, the tuberculous invasion was found to be confined to one kidney in thirty-eight instances out of sixty-seven cases. With the aid of the expert cystoscopist not only will the diagnosis be earlier and oftentimes more certainly determined, but its one-sided character can positively be arrived at, and also important information may be obtained as to the condition of the bladder[2]—often a doubtful point because the irritation of the renal discharge often simulates a calculus, a tumor, or a tuberculous cystitis. From the aid derived from this mode of examination, with its ureteral interrogation, earlier operation becomes, not only possible, but greatly advantageous in sparing the bladder and the opposite kidney from probable secondary infection. This is self-evident, and to it, it is hardly necessary to allude. Of far more weight is the following question: Having accomplished the extirpation of a tuberculous kidney, or having performed nephrotomy for the relief of an abscess or abscesses, what final result may be expected? Experience has accumulated much clinical data in answer to this question, though a large amount is not of as positive a character as one might wish. Albarran, for instance, reports eight nephrectomies for tuberculosis with one death from the operation. Of the remainder, five patients were living and in good condition from fifteen to thirty months afterward. He also performed nephrotomy eleven times for tuberculous abscess, eight of these patients dying three to seven months thereafter. This, with him, is an argument against the procedure and in favor of primary nephrectomy. Guyon recently reported twenty primary nephrectomies for tuberculosis, resulting in eleven deaths and seven absolute cures. Israel reported at the Moscow Congress twenty nephrectomies for tuberculosis with eight deaths. Of the twelve in which operation was successful, six patients were alive and well two years and over, and six were living one year thereafter. One does not find much collected information on this point, and on the finer one, of any proper appreciation of the value of extirpations in the beginning of a tuberculous renal lesion, we can find little or nothing of service. In most of the cases so far published there have been advanced lesions, and to a certain extent associated damage to the ureter, and even to the bladder, which organs have been either left untouched surgically to be cured by Nature's subsequent efforts (which are, I believe, as potent an influence for good in the genito-urinary tract as in the lungs), or have been dealt with by a later surgical attack (Kelly, Israel, and others). Suffice it to say, that if a patient complains of lumbar pain, with a sense of weight and dragging, extending to the inguinal region, with some nausea and anorexia and slight emaciation, though without the characteristic symptoms of renal colic, renal sand, renal catarrh, or malignant disease, pyelitis, pyonephrosis or hydronephrosis, the urinary sediment should be frequently and carefully examined for tubercle bacilli by a competent bacteriologist, and an early cystoscopic examination and catheterization of the ureters should be methodically carried out. On the microscopic demonstration of tubercle bacilli alone, however, too much dependence should not be placed; for Leyden[1] has recently stated, and in this opinion several authorities concur, that the tubercle bacillus so closely resembles in appearance and staining properties the smegma bacillus, which is often found in urine, and almost always in cystitic urine, that the microscopic evidence should always be confirmed by inoculation experiments. Pousson[2] gives a beautiful description of a case in which he was able to follow the history for months, through what he called the hemorrhagic stage, and into the purulent stage, for he believes that many cases of "renal phthisis," like many of "pulmonary phthisis," pass through an era of congestion and hemorrhage before one of suppuration develops. Such instances might be multiplied. Even though no bacilli are found in the urinary sediment the cystoscope may show congestion of one ureteral opening, or circumscribed patches of inflammation or superficial ulceration, between this and the urethra. Moreover, by the analysis of the urine from each kidney, which may thus be obtained, positive evidence will often be furnished of the state of both kidneys, and early nephrotomy may be performed if necessary. The success which may be expected to follow such treatment is illustrated in a case recently reported by Meyer.[3] On the other hand the difficulties frequently associated with such examinations were brought out in a case of my own in which the same acknowledged expert kindly officiated and only obtained knowledge of the condition of each kidney after six protracted trials (Case XV.). Un-

[1] *Deut. Arch. klin. Med.*, vol. lv, p. 449, 1895.

[2] Kelly (*Annals of Surgery*, January, 1898) has shown that an endoscopic tube may be introduced in the male bladder, and with the patient in the knee-chest position the viscus becomes distended with air, as in women, and its interior may then be fairly well explored. This is a cheaper, easier, and readier method than that in which the cystoscope is used.

[3] MED. NEWS, vol. lxx, p. 545, 1897.

fortunately, in only two of the nine cases of renal tuberculosis in which I have been called upon to operate was the patient observed at so early a stage as has just been indicated. In one of them (Case XXIX.) the illness was said to be of only three-months' duration, but in this case as well as in others presenting a history of illness lasting from one to several years, the kidney was thoroughly diseased and its condition was diagnosed by ordinary means. In six of these cases an attempt was made to relieve the symptoms by means of nephrotomy, either as an end in itself when the tuberculous nature of the trouble was not absolutely established, or to enable the patient to get into a better condition for a subsequent nephrectomy, a procedure which, though frowned upon by Albarran, is, I still believe, of decided benefit in certain cases. Twice with me, nephrotomy has been followed by a permanent cure. These cases (Nos. XXVI. and XXVII.), from the associated symptoms of tuberculous arthritis, cough, etc., were considered to be tuberculous and they are so classified. The patients were seen in robust health eight and nine years after operation. In both the sinus in the operative area remained open two years and then healed permanently. In another patient, upon whom nephrotomy was performed, the sinus healed only to reopen, and in this instance, as well as in three others, the continued fever, purulent urine, and general emaciation rendered necessary the more radical nephrectomy. Of the six patients from whom I removed the kidney for tuberculosis, one (Case XXIX.) survived this operation only a short time. One died suddenly within a month from complete suppression of urine, and four are in good health to-day, twenty-eight, sixteen, fourteen, and eight months respectively, after the date of the operation.

Although success may rarely follow the lesser operation of nephrotomy, it is not unknown, and only last year Vanderveer[1] described a case in which he drained and irrigated a tuberculous abscess of one kidney, and obtained an apparently perfect cure, the wound healing and the urine becoming normal. Israel[2] has also recently reported a case in which he successfully removed a portion of one kidney for tuberculosis, stopping the hemorrhage by digital compression.[3] However, in most cases there are multiple tuberculous foci, solid or in abscess form, and the necessity for removal of the entire organ exists. Thus, in Case XXXII., wherein half the bladder was at first removed for tuberculous infection, with a nephrotomy for renal abscess, though there was a complete closure of the lumbar wound this apparent cure was of brief duration. The sinus reopened, and it was necessary to remove the disorganized kidney. In a few months thereafter the patient made rapid gain in weight, and when seen one year afterward, he weighed seventy pounds more than at the time of his last operation, and at this time both renal and bladder incisions were closed, and further, tubercle bacilli were not to be found in the urine, which was clear and passed every two or three hours, thus marking the capacity of his diminished bladder.

[3] *Jour. Cut. and Genito-Ur. Dis.*, vol. xiii, p. 33, 1895.

The removal of a tuberculous ureter has been proposed and carried out, first by Reynier[1] in 1893, and in 1896 by Kelly,[2] either through an abdominal incision or by a lumbar nephrectomy, the upper part of the ureter being removed with the kidney and the lower part by a prerectal or vaginal incision; or—the operation which Kelly now prefers—by an oblique incision parallel to, but somewhat above, Poupart's ligament. Through this opening the peritoneum may be peeled off and pushed up until the kidney and the entire ureter are dissected out extraperitoneally. A similar procedure was commended by Reynier. This ureterectomy may be performed at the time of the nephrectomy or left to a later time. Occasionally a thickened ureter, under such circumstances presumably tuberculous, will not cause further trouble. This was the condition in Case XXXIV. The depressed condition of the patient at the termination of the operation, a nephrectomy, compelled me to leave *in situ* a much thickened and obviously involved ureter; but her great improvement in health leads to the belief that Nature's powers have been able to neutralize the remaining infection. A similar condition of ureteral involvement was left untouched in Case XXXI., and has apparently been safely cared for by the *vis medicatrix naturæ*.

CASE XXVI. *Tuberculosis (?)—Pyonephrosis—Nephrotomy—Recovery.*—Mary F., aged twenty-three years, noticed during the nine months previous to coming under observation a decreased quantity of urine, some vesical irritation, and later, pain; and more recently, a smooth swelling in the right loin. Micturition increased up to fifteen times daily. Once a small amount of blood followed urination. Cough and night-sweats had existed for two months. The urine was acid, of a specific gravity of 1028, and contained no albumin. Its sediment consisted of pus-cells, epithelium, and calcic oxalate crystals. No tubercle bacilli were found.

May 24, 1888, a three-inch oblique incision exposed the distended right kidney. A needle drew pus, and by an incision made into its pelvis, ten ounces of pus was evacuated. No calculus was found. A drainage-tube was left in position. The patient made an excellent recovery. The flow of urine through the wound quickly ceased, and on her discharge from the hospital, three weeks after the operation, the sinus was not apparently more than an inch deep. It, however, remained open for nearly two years and then healed under the persistent use of injections of diluted tincture of iodin. Eighteen months after the nephrotomy the patient developed a tuberculous abscess of the lower end of the tibia, which continued two years, but which terminated in recovery. She was last seen during December, 1897, and was in good health. The kidney was still slightly enlarged. The scar was firm, and there was no weakness of the lumbar region or yielding on expulsive effort. This case was doubtless one of tuberculous abscess, though this could not be proven by the demonstration of the bacillus.

CASE XXVII. *Tuberculous Abscesses of Kidney—Nephrotomy—Recovery.*—Florence S., aged twenty-five years, entered New York Hospital, July 17, 1888, and presented a tuberculous family history and a personal history of an illness of sixteen months, marked by persistent cough and expectoration, by painful and frequent

[1] Reynier, *Rev. de Chirurgie*, p. 272, 1893.
[2] *Bulletin Johns Hopkins Hosp.*, February and March, 1896. See also Hartmann, *Rev. de Chir.*, Nov., 1897; and Gerster and McCosh, *Annals of Surg.*, Sept., 1897.

micturition, and pain in the right loin. These symptoms were increasing, and were associated with decided loss of strength. Examination showed two rounded masses in the right lumbar region, connected, and rather tender. and projecting below the liver. The general condition of the patient was bad.

July 18th the right kidney was exposed by a slightly oblique incision and aspirated. Pus was withdrawn, and an incision into its pelvis showed the kidney to contain numerous abscesses. The intervening septa were broken down, and about a pint of pus evacuated. The kidney was irrigated, and a drainage-tube inserted. The general condition of the patient was somewhat improved by the operation, though suppuration and fever continued. The amount of pus in the urine became less and the tumor gradually shrank in size. When the patient was discharged from the hospital, about eight weeks after operation, the urine still contained pus, and occasionally blood, and the sinus in the loin had not closed. This remained open nearly two years, the discharge of pus growing less. Improvement was hastened by injections into the sinus of tincture of iodin and water (one part to three). Since the wound healed the patient has enjoyed good health. She was last seen during December, 1897, having gained greatly in weight. In this case there was also, most probably, a tuberculous infection, though such was not satisfactorily proven.

CASE XXVIII. *Tuberculous Abscesses of the Kidney—Nephrotomy—Subsequent Nephrectomy—Death.*—Mary D., aged twenty-five years, entered New York Hospital during May, 1892, with a history of cystitis of one-year's duration. Eight months after the beginning of her illness she married, and from that time grew much worse, having involuntary micturition and loss of strength. Ten days before entering the hospital her physician discovered a round, smooth, and slightly fluctuating tumor in the right side of the abdomen, and in its lowest portion it was covered by the distended colon. The urine was full of pus.

May 25, 1892, a four-inch transverse incision was made in the right lumbar region and the greatly distended kidney was exposed. It was incised, and three distinct abscess cavities were washed out and drained. The amount of kidney substance remaining seemed very small. Plenty of gauze was used for drainage. The pus from the kidney contained staphylococci, but no tubercle bacilli. The patient did not rally well after the operation, and it was noticed that the kidney remained much enlarged. There was a daily fever of about 102° F. June 13th, Dr. Bull, who was in charge of the service in my absence, explored the sinus, broke into more abscess cavities, and inserted two large rubber drains. Still the condition of the patient did not improve, and six weeks later Dr. Stimson removed the purulent kidney. The patient could not, however, stand the shock of the operation, and died the following day.

The extirpated kidney measured 18x6x4 cm. Its surface was smooth, but bulging in many places. The lining of its pelvis was everywhere in a state of cheesy degeneration, and numerous similar areas were scattered through the kidney substance, many of which were in communication with the pelvis of the organ. The microscopic appearances were those of tuberculosis.

CASE XXIX. *Tuberculosis of the Kidney—Abdominal Nephrectomy—Recovery.*—Frances G., aged nineteen years, was seized in December, 1893, with a sharp pain in the right lumbar region, without known cause. This was followed by fever. The pain and fever continued, though there was but slight tenderness over the affected region. There was increased frequency of micturition. Three months after the initial symptoms a movable tender tumor the size of a cocoanut was discovered in the right side of the abdomen, reaching below the umbilicus, and leaving a space between it and the ribs above. The urine was of a specific gravity of 1008, and contained a trace of albumin and some pus and blood-cells. On account of the rather unusual position and from the size of the tumor, an exploratory laparotomy was performed March 17, 1894. A two-inch incision over the tumor disclosed a displaced kidney, which was nodular and greatly enlarged. The peritoneum was incised, external to the ascending colon, and peeled off the kidney, which organ was freed and lifted out of its bed. The pedicle was ligated with catgut, the ureter and vessels being separated for that purpose. A counter-opening for drainage was then made in the lumbar region, and both openings in the peritoneum were closed by sutures, as was the laparotomy wound. There was a quick recovery from the operation. The abdominal wound healed by first intention, and within eighteen days the patient was up and passing daily about forty ounces of urine. Examination of the urine showed that it still contained a large amount of albumin, some blood, casts, and many tubercle bacilli.

Three weeks after the operation occasional vomiting occurred and persisted. The quantity of urine decreased steadily, and the patient died in the middle of the fourth week in uremic convulsions. No autopsy was permitted. The extirpated kidney showed several caseous abscesses and ulceration of its pelvis.

CASE XXX. *Tuberculous Pyonephrosis—Nephrotomy—Subsequent Nephrectomy — Recovery.*—Lilly C., aged twenty years, began to have pain in the left side of the abdomen during the summer of 1893. The following spring she had a severe attack of cystitis with pus and blood in the urine, and suffered on several occasions from intense pain in the left lumbar region. These symptoms grew worse, and there was also pain in the right side and in the back. For two weeks before her entrance to the hospital, December 20, 1894, she had noticed a swelling in the right side of the abdomen. Physical examination showed her to be pale, thin, and weak, with a temperature varying from 99° to 104° F. Nearly the whole of the right upper quadrant of the abdomen was occupied by a soft, fluctuating, tender swelling, apparently due to a distended kidney. The urine was light colored and cloudy, though acid, and was of a specific gravity of 1018, and contained eighteen per cent. of albumin by volume. It also contained much pus.

December 23, 1894, a slightly oblique incision was made in the right loin, and the kidney was exposed and incised. A great quantity of pus escaped, especially after the septa between the walls of the numerous abscesses were broken through. On account of free hemorrhage the cavity was firmly packed with gauze. After the operation the patient became somewhat more comfortable, but the urine still contained about ten per cent. of albumin, and the temperature elevations continued, though not so high as before. Nephrectomy was, therefore, performed January 5, 1895. From the lower end of the former wound a transverse incision was made forward, and the kidney exposed, dissected free, and removed, the pedicle being ligated with silk. The fresh wound was sutured and a gauze drain placed in the old opening. On the fifth day the gauze was removed and the cavity irrigated. Three weeks after the operation the patient still had an afternoon temperature of 102.5° F., but her general condition seemed much improved, and the urine contained only occasionally a slight trace of albumin. February 17th tubercle bacilli were demonstrated in the

urine. There was also vesical tenesmus, an afternoon fever, and the general condition was not good. By her own request the patient was removed to her home. The ligature of the pedicle had not come away. Death followed six weeks later, about three months after the operation. The excised kidney was found to present the lesions of the various stages of tuberculosis. It was evident that the other kidney was likewise involved in the infection.

CASE XXXI. *Lumbar Sinus—Tuberculosis of Kidney—Nephrectomy—Recovery.*—Eugene L., aged twenty-two years, entered New York Hospital, October 29, 1895. He had received a kick in the left lumbar region when seventeen years of age, and thereafter there was always more or less pain in that situation. Two weeks after the accident a tender and hard swelling formed, which grew softer in time, and after two years was opened and a quantity of pus evacuated. For a year the sinus persisted and then closed in part, with increase in pain. During April, 1895, it was scraped, and it then gradually closed so that for the five months preceding the operation shortly to be described there was no discharge at all. Pain during this time was growing constantly worse, so that the patient had now been disabled for some months. Otherwise the health had been good; there were no disorders of digestion, no symptoms referable to the bladder, and no chills. There had been a loss of ten pounds in weight in the year preceding admission to the hospital. Examination of the urine showed it to be absolutely normal, except that the sediment contained the crystals of triple phosphates and ammonium urates.

October 30, 1895, a transverse incision was made midway between the crest of the ilium and the last rib, and to gain more space another incision was made directly upward from the middle of the first. In dissecting free the adherent kidney both the pleural and the peritoneal cavities were accidentally opened, and were immediately closed by stitches of fine catgut and silk. No immediate or secondary bad effects followed the accident, which may be considered, from the experience of others, as well as my own, to be usually without unfavorable sequelæ. The kidney was entirely separated and finally brought out through the wound, and it was found to be riddled with abscesses. Its pedicle was ligated *en masse* with strong silk, and the kidney was removed. The transverse incision was sutured, and the other left open for the abundant gauze drains.

Recovery from the operation was prompt. The urine contained a little albumin for a few days, but this entirely disappeared later. The dressing was changed on the second day and the drains were removed on the fifth day. No symptoms developed referable to either the pleural or peritoneal cavity. Six weeks after operation the patient left the hospital much improved in health. There was still a small sinus in the loin. The kidney was not much enlarged, but was almost entirely composed of cheesy and calcareous material separated by fibrous septa. No renal tissue was apparent on gross inspection. Microscopically a few shrunken tubercles were found in the fibrous tissue, but the diagnosis of tuberculosis was not absolutely verified by the pathologic examination.

CASE XXXII. *Extensive Tuberculosis of the Bladder and Kidney—Resection of One-half of the Bladder—Nephrotomy—Nephrectomy — Recovery.*—Frederick T., aged forty-four years. For two and one-half years this patient suffered from attacks of renal colic on the right side, the pain extending from the lumbar region into the pelvis. The attacks increased in severity, and were accompanied by nausea and frequency of micturition. The urine contained much mucus and blood; it was acid, of a specific gravity of 1024, with ten per cent. of albumin (by volume), and its sediment contained blood and pus. By palpation, the bladder seemed somewhat thickened and very tender.

June 12, 1896, a cystoscopic examination was made, and a tumor was seen to occupy the posterior wall of the bladder. Suprapubic cystotomy was performed. The tumor was soft and sessile and bled readily. It occupied the posterior wall of the bladder, covering an area about 1½ inches in diameter, and reaching to within ½ an inch of the ureteral openings. The peritoneum was dissected off from the bladder to the prostate, and on each side to the vas deferens; then a triangular portion of the whole thickness of the bladder, including the new growth, was resected, the incisions being everywhere in the healthy portions of the bladder-wall. Thus, the bladder between the ureters and the whole top, making about one-half of the viscus, was removed. In peeling off the peritoneum two openings were torn in it. These were promptly closed with silk. The hemorrhage from the divided bladder-wall was quite free, but it was quickly controlled by the catgut sutures, which, passing through the entire thickness of the bladder, closed its posterior portion to the summit, which was left unsutured. Gauze packing was then placed between the sutured bladder and the stripped-off peritoneum, and a Mikulicz drain was inserted in the bladder itself. By a lumbar incision the right kidney, which two days before had been recognized as enlarged, was then opened, and three ounces of pus evacuated from its pelvis. Drainage was here secured by gauze and a rubber tube. The wounds were dressed daily. The gauze in the bladder was soaked daily with Thiersch's solution. It was removed on the fifth day. Within ten weeks both wounds had completely healed. The bladder held two ounces of injected fluid. Eleven weeks after the operation the patient passed a black silk suture covered with phosphates. All the others used were of catgut. This one had accidentally been applied. August 29th he left the hospital and went home, returning two months later somewhat emaciated, and with lumbar and suprapubic sinuses now open and discharging pus and urine. On several occasions the urine was examined for tubercle bacilli; once with a positive result. The vesical sinus was also found to be tuberculous. There was an afternoon rise of temperature of 100° to 104° F. The kidney-tumor was still marked and tender.

Nephrectomy was determined upon as affording him a chance of relief, and November 25, 1896, the old lumbar scar was incised, and as the adhesions were extensive, the kidney was peeled out of its capsule. The vessels and ureter were tied together with strong silk. The wound was partially sutured and drained with gauze packing. The division of the ureter showed suspicious thickening, and as far down as it could be palpated it was found to be much enlarged. The patient's condition, however, did not permit extirpation of the affected ureter. Examination of the kidney showed it to contain numerous tuberculous abscesses. To overcome the tardy separation of the ligature on the pedicle of the kidney it was tied around a small flattened rubber ball, and the tension thus secured by the elasticity of the rubber brought it away in about five days.[1]

Six months later the patient had vastly improved. He had gained forty pounds in weight. The suprapubic fistula was still open, but contracted to the size of a needle. The urine was retained for two hours and discharged in the day time entirely through the urethra. By night there was often leakage. The urine was still cloudy, but less so.

[1] Weir, "The Extraction of Too Long Retained Silk and Silkworm-gut Ligatures and Sutures," the MEDICAL NEWS, April 3, 1897.

It was acid and contained two per cent. of albumin (by volume), and was of a specific gravity of 1020. No enlarged ureter could be felt on palpation.

December 8, 1897, the patient again reported for inspection. He had gained ninety pounds, and weighed more than he ever had before. He said that he could hold his urine from two to three hours, and when discharged it was clear. Two examinations of the urine failed to detect any bacilli. Both the lumbar and suprapubic wounds had solidly healed.

Case XXXIII. *Tuberculous Pyonephrosis—Nephrotomy—Subsequent Nephrectomy—Recovery.*—Mamie D., aged twenty-seven years, gave birth to her only child when she was twenty years old, and was afterward troubled with attacks of pain in the right side, with occasional chills and fever. During March, 1896, six months later, she entered New York Hospital, where a diagnosis of probable pyosalpinx was made by my predecessor, and on September 24, 1896, an exploratory laparotomy was performed. Nothing warranting the removal of a tube was found. and the wound was closed. On my return to duty on October 1st, I found that the pain had continued, and was then referred to the region of the right kidney, which could be palpated bimanually and was tender on pressure. The urine was cloudy, acid, and of a specific gravity of 1015, and contained five per cent. of albumin (by volume). The sediment contained abundant pus and blood-cells. October 10th an enlargement of the right kidney could be clearly defined, and a curved lumbar incision was made, the organ in question being exposed and incised. Three or four ounces of pus escaped, the cultures from which contained the bacillus coli commune, and staphylococcus aureus. The wound was drained with gauze and not sutured. On the fourth day after operation there was a sharp rise of temperature, which then recurred daily, and was at first considered to be due to the drainage, which was not entirely satisfactory. This was corrected, and four weeks later the gauze packing was discontinued. There then remained but a small sinus. Meanwhile every afternoon there was a daily temperature of 101°–103° F., and the urine contained from one to four ounces of pus. The patient's condition was rapidly deteriorating. Nephrectomy was, therefore. decided upon, and performed December 31, 1896.

At the operation the finger was thrust into the old sinus and much pus escaped. The incision was then prolonged above the crest of the ilium and the kidney dissected out by means of the fingers. The pedicle was clamped and tied, the ligature including the loop of a galvanocautery in order to subsequently divide and release the silk ligature (Cleveland's method). There was left on the stump about three-fourths of an inch of kidney substance. A rent in the diaphragm, near the tip of the twelfth rib, was sutured with catgut. A Mikulicz drain of iodoform and sterilized gauze was tightly packed into the wound. The patient was a good deal depressed by the operation, but rallied under stimulating treatment.

January 1, 1897, the patient passed 25 ounces of urine of a specific gravity of 1028, and containing only a trace of albumin. On the succeeding days the amounts were 47, 54, 66, 67, 48, 43, 30, 21 ounces, and from then on the quantity varied from 25 to 45 ounces daily. On the third day the packing was all removed, except the outer layer of gauze. On the fifth day, the wire loop was burned through the ligature, which was then removed. Recovery was slow, and there continued to be a daily afternoon temperature of 100° to 102° F. The patient left the hospital February 15, 1897. The last urinary examination showed the urine to be turbid, acid, of a specific gravity of 1012, and free from albumin. There were a few pus-cells and several tubercle bacilli in the sediment. There was a line of unhealthy granulations in the loin about three inches long into which a probe sank a couple of inches in several places, though no distinct sinus seemed to exist. Pressure over the pedicle and ureter was painful. The extirpated kidney measured 10x5x3 cm., and contained several abscesses and hemorrhagic areas. Microscopic sections showed typical tuberculous lesions throughout nearly the whole organ. The patient was reported January 1, 1898, as improving steadily, but until then the fear existed that the remaining kidney was similarly affected.

Case XXXIV. *Tuberculous Pyonephrosis—Nephrectomy—Recovery.*—Alice B., aged twenty years, kindly referred to me by Dr. Messoner, presented a history of gradually progressive loss of flesh and strength during the previous two years, and without assignable cause. There was more or less constant pain in the right lumbar region, and an increased frequency of micturition, with very great tenesmus. Lately there had been noticed a plainly palpable tumor occupying the seat of the right kidney. There was an afternoon fever, sometimes reaching 104° F. The patient had hip disease at the age of ten years, with multiple bone abscesses, and somewhat later a tuberculous ulceration of the sternum. The urine, of which from 50 to 60 ounces were passed in the twenty-four hours, was pale, and contained a stringy sediment, albumin, and pus.

June 15, 1897, lumbar nephrectomy was performed by the usual curved König's incision. The kidney was exposed and freed without difficulty; its pedicle was ligated and the organ removed. The ureter was separately ligated with catgut. In order to facilitate the removal of the silk ligature from the pedicle at will, Grad's[1] procedure was adopted. On the sixth day, the ligature was untied by means of the tractor threads and removed with ease.

The temperature fell after the removal of the badly diseased kidney, and except for a most annoying irritability of the bladder which various remedies failed to benefit the patient made a good though slow convalescence. Five days after the operation, when it was possible to measure the urine, it being then passed in amounts of an ounce or less, the daily quantity was 41 ounces. From this time on this amount varied from 35 to 55 ounces. Vesical pain and tenesmus continued to annoy the patient long after she was up, and after the wound in the loin had healed. November 5, 1897, five months after the nephrectomy, she had gained in weight and in the ability to retain the urine, and the scar in the loin, which once opened after closing, was solid and not tender.

The kidney in this case was filled with large caseous nodules of tuberculosis, with almost total destruction of the renal substance. Tubercle bacilli were found in large quantities.

(To be continued.)

MEDICAL PROGRESS.

A Case of Rabies with a Prolonged Incubation.—Feltz and Archambaud (*Gaz. Heb. de Med. et de Chir.*, September 30, 1897) give the notes of a case of rabies occurring in a young man, aged twenty years, who died in wild delirium within thirty-six hours after the initial symptoms of the disease appeared. No history of a dog bite was obtained, and the correct diagnosis, although suspected, was not fully established until after death. Then, in questioning the parents, it transpired that the young man had been

[1] *Amer. Gynec. and Obstet. Jour.*, February, 1897.

bitten in the mouth six months previously. The animal by which the bite was inflicted was found to have rabies, and a child bitten by it was treated at the Pasteur Institute and recovered. The case of the young man is remarkable on account of the long period which elapsed between the slight bite of the dog, and the fatal disease of the man. There was no possibility that fear caused the illness, as neither the patient nor the parents suspected its nature until after death had occurred.

In this connection it is interesting to note that POTTEVIN (*Centralb. für Bakter., etc.*, October, 1897) says that during 1896, 1308 persons were treated at the Pasteur Institute of whom 4 died, giving a mortality of 0.3 per cent., and making the total mortality since 1886 a fraction under 1 per cent. Bites in the face gave a larger mortality than wounds of other parts of the body. Since the establishment of the Institute 3096 foreigners and 15,549 natives have been treated in the Paris institution. It will thus be seen that the number of persons treated last year is considerably below the average for the ten years in which the Institute has been open. This is due, no doubt, to the establishment of similar institutions in other cities rather than to the fact that treatment for rabies is becoming unpopular.

An Official Employment of Formaldehyd Disinfection.—DR. MACKENZIE of Leith, Scotland, was one of the first medical officers of health to employ the formalin spray system for room-disinfection. He reports that he has found that the general results of the spray disinfection with formalin are entirely satisfactory. "Of some 400 houses, or rooms, disinfected, I can say that not in any instance has infection been contracted after spraying. In one or two instances the fever was caught before spraying, and developed symptoms on the same day as the house was disinfected. But in this case the original patient had remained at home. But where the patient is removed and the house disinfected, a second case is practically unknown. Further, a hospital pavilion was used from September, 1896, to May, 1897, for scarlet fever—say about 120 cases. I had the pavilion sprayed with two-per-cent. formalin solution, and a week afterward, or less, placed patients with measles there. During three months of measles, about thirty cases, not a single suspicious sore throat, rash, or indication of scarlet fever occurred. Similar experiments have been repeated with a smallpox ward, several times in diphtheria wards, erysipelas wards, etc. In no case have I found any suspicion of infection. The precise facts will be published later in the annual report for 1897."

Removal of Foreign Body from the Trachea by Means of a Tube.—SEVESTRE and BONNUS (*Rev. de Therapeut.*, December 1, 1897) were called upon to treat an infant who had sucked into its trachea a small glass bead. A tube was passed through the larynx and the foreign body was expelled through it. If this maneuver had not been successful tracheotomy would of necessity have been performed.

Cure of Prolapse of the Female Urethra.—WOHLGEMUTH (*Deut. med. Wochenschr.*, November 4, 1897) has been most successful in his treatment of obstinate cases of prolapse of the female urethra by means of the thermo-cautery. The cauterizations should extend radially, that is, they should be made in the longitudinal axis of the urethra, and should extend throughout the whole of its thickness. By the cicatricial contraction which follows, the prolapse is completely obliterated, though in some instances repeated applications are necessary. The advantages of this simple procedure are: the fact that it requires no especial antiseptic precautions; that it obviates the necessity of leaving a catheter in the bladder, and that there is no danger from hemorrhage during the operation.

THERAPEUTIC NOTES.

Treatment of Chronic Ulcers of the Legs.—LANGSEORFF (*Centralbl. f. Chirurg.*, November 20, 1897) has treated over 200 ulcers of the leg, without a single failure, by means of the following method. The leg is rubbed with green soap, washed and dried. The ulcers are then dusted thickly with calomel, which is stirred to a paste with a wet cotton swab. Fine salt is then dusted upon the paste, and is in turn mixed with it. By this means corrosive sublimate is formed which in its nascent state acts very energetically, and for three or four hours causes a strong burning sensation, which in a nervous patient may require a morphin injection. On the following day the granulations are completely burned off, and there is presented a clean wound, with possibly a small slough in its center, which soon separates. Pain has entirely disappeared. Under a stimulating salve containing turpentine, and with as complete rest in bed as is possible, the ulcer is quickly covered with epithelium. Only occasionally is it necessary to touch excessive granulations with a crystal of cupric sulphate. It sometimes happens that the ulcer partially closes and then the healing process comes to a standstill. In these cases a solid salve is spread upon a visiting-card and bound firmly upon the ulcer. From the effect of the moisture the callosities quickly dissolve and the growth of epithelium is resumed. In only two cases of the series were Thiersch grafts found necessary. After healing is complete the leg and foot are covered with zinc salve as high as the knee. This dressing is left in position two weeks. A good effect is also produced by this treatment in eczema of the lower extremities associated with numberless minute granulating ulcers. In these cases the calomel and salt are mixed to a paste, and spread upon the leg which has previously been scrubbed with green soap and water to remove all fat from the ulcers.

For Alopecia Areata.—PANICHI (*Centralbl. f. die gesammte Ther.*, December, 1897) treats alopecia areata with a mixture of three or four parts of a solution of carbolic acid, and six or seven parts of tincture of cantharides. This mixture is not only rubbed daily on the bald areas, but is injected by means of a syringe into the skin every four to six days, so as to exert an influence directly upon the hair-follicles.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

A NEW TERROR FOR MEDICAL STUDENTS.

Under this heading the *Medical Press* depicts the discomfort the medical student is destined to experience when called upon to discuss, in his final examination, the diagnosis which he has formed of an injured joint by the aid of his trembling fingers, when confronted by a shadow on the screen of a fluoroscope, which in all probability will display appearances very much at variance with his previously expressed opinion. It is trying enough, remarks this writer, to be asked, with one's brain still in a muddle from the final "crams" to identify the various organs and tissues which are exposed to view in an artfully dissected subject, but it will be vastly more disconcerting to be required to outline and describe the organs by the aid of an X-ray screen. A further extension of the present curriculum may become necessary to enable the student to familiarize himself with the various innovations in matters diagnostic, and the time is probably not far distant when X-ray diagnosis will become a special item of medical education. A stage later, the candidate may be shown a pulsating something dimly visible through the thoracic cage, and asked to say whether it is the heart, the aorta, or an aneurism.

On first thought, this all impresses one as being something only possible in the very remote future, but to those attendants at the recent meeting of the Medical Society of the State of New York who had the good fortune to witness the demonstration of the X-ray and its use in surgery and in medicine, it was evident that the experience described by the writer in the *Medical Press* awaits the medical student at no distant day. The practical use of the X-ray in surgery is now quite familiar to all advanced surgeons, but its usefulness in medicine as an aid in securing greater exactness in discovering the extent and nature of pathologic lesions in the organs and soft tissues, as demonstrated by Dr. Francis H. Williams of Boston, awakened no little surprise. Indeed, his skiagrams, showing the presence of tuberculous deposits, pleuritic exudates, and the delicate differential diagnosis between a dilated and a hypertrophied heart, were marvels of expert skiagraphy and a convincing demonstration of his contention that more definite information can be obtained in regard to these and similar conditions by the use of the X-ray than by percussion and auscultation.

THE SCOPE OF THE MARINE HOSPITAL SERVICE.

It is often stated by those who are opposed to the Marine Hospital Service, and it is uttered with all the solemnity of a final pronunciamento, that the Service was originally established to care for sick and disabled seamen, and is, therefore, incapable of performing other or allied functions. When this had been uttered, the final blow was thought to have been dealt to the Service by those who are interested in opposing its development.

That it was originally established for the purpose named is true, but to assign that as a reason why it is incapable of performing other functions is both unimportant and superficial. The care of sick and disabled seamen brings the officers of the Service into intimate relations with the hygiene and sanitation of ships, and the history of the Service abounds with records of investigations made into these subjects, which are so closely allied to quarantine. Long before the Marine Hospital Service was entrusted with the duties of enforcing National quarantine laws, its officers had made both official and unofficial investigations into the cleanliness of ships, the hygiene of

the forecastle, sanitation of crews, examination of the food-supply of deep-sea vessels, all of which may be found in the annual reports, which have been issued for the past quarter of a century. So far from disqualifying officers for the work of a public-health service, particularly in its relation to maritime quarantine, the intimate and almost indispensable connection with the functions of a public-health service peculiarly fits the officers for the performance of such duty, and the active participation by them in such work during the period named makes them what unbiased persons regard them to be—the only corps of medical men in this country specially skilled in the class of work in question. The very foundation of a system of safeguards for the National health is a protection of the interior of the country from the introduction of contagious disease from without. The Service which, since its foundation, has dealt with "men that go down to the sea in ships," and with the condition of ships themselves, is the one best fitted by long and practical experience to deal with the question of maritime quarantine.

This is not all. Along the line of natural development The Marine Hospital Service has progressed, by direct authority of Congress, in other fields of investigation and execution in respect to public-health functions, and besides its original work of caring for sick and disabled seamen (of which over fifty thousand are treated annually), keeping officers in touch with active professional work, it has performed its functions as the Federal agency in the management of quarantine; undertaken investigation of smallpox by direction of Congress, the results of which study are ready for publication; has collected and published data respecting health and mortality statistics throughout the United States and the world, the last by the reports of the Consular service. It has also been engaged for the past year or more in experiments in car sanitation with respect to communicable diseases; has conducted investigations concerning the pollution of water-supplies; peformed pioneer work in this country in respect to diphtheritic antitoxin and formaldehyd disinfection; and two of the officers are now in Havana, Cuba, by detail of the President, conducting an investigation into the causation of yellow fever. These varied duties which it has performed and is now performing, certainly indicate the variety of its work in connection with public health service. Its hygienic laboratory is one of the best equipped in the country, and here every year, in turn, several officers receive instruction bearing upon the advances in hygiene, bacteriology, and allied sciences. These facts should certainly satisfy any reasonable professional man that the scope of the Service is sufficiently varied, and that it is entitled to the sympathy and support of the medical profession throughout the country in its development and progress.

Any movement which has for its cardinal text the relegation of the Marine Hospital Service, which has done so much pioneer work in the interests of public health, to a secondary or even more obscure position in the ambitious plans of its enemies will not meet with a responsive chord in the minds of the majority.

The Service is developing in the exact direction which the promoters of the proposed Department of Public Health expect to attain by one act of legislation.

The Senate, upon the recommendation of its Committee on Public Health and Quarantine, has already indefinitely postponed two bills for the establishment of a Department of Public Health, and favorably reported the Caffery bill, which imposes additional powers and duties upon the Marine Hospital Service. In view of the state of the National finances and the improbability of Congress assenting to the large and indefinite expenditure necessary for the establishment of a Department of Public Health, it seems to us that the profession should turn its attention to developing and supporting the Marine Hospital Service as the public health service *de jure* as well as *de facto*, and that those who are now, as we think, mistakenly, if honestly, expending their efforts in the attempt to create a Department of Public Health should join with their fellows in strengthening the hands of their professional brothers in the Marine Hospital Service who have been so long and faithfully serving the public.

ECHOES AND NEWS.

Death of Dr. Pean.—The death of Dr. Jules Emile Pean, the eminent surgeon and gynecologist, is announced as occurring in Paris on the 30th ult.

Typhoid Fever in Jersey City.—During the past month more than seventy-three cases of typhoid fever have been reported in Jersey City. Dr. Thomas H. Atkinson is one of the latest victims, and his condition is very critical.

Concentration in the New York City Board of Health.—The Board of Health has abolished the local boards of Newtown, Jamaica, Hempstead, and Flushing, and removed all their employees with the exception of Dr. P. J. Maynard, health-officer of Flushing.

Smallpox in the South.—At Atlanta, Ga., the health authorities seem to have checked the spread of smallpox, only twelve new cases being reported there during the week ending January 29th. In Alabama the disease is on the increase, and 175 cases were reported to the Board of Health during that period of time.

Officers of the New York Medical League.—At the recent annual meeting of the New York Medical League, the following officers were elected: President, Joseph E. Janvrin; vice-president, F. R. Sturgis; recording-secretary, J. C. Schminke; corresponding-secretary, Douglas H. Stewart; treasurer, E. Eliot Harris.

Memorial Services to Mr. Ernest Hart.—A memorial service was held on Tuesday, January 11th, at Mary-le-Bone Parish Church, London, and the address was delivered by Canon Barnett, who tenderly reviewed Mr. Hart's career and admiringly depicted the manysidedness of his activity. A large number of scientific and medical men were in attendance, and thus paid this last mark of respect. At the conclusion of the service the body was removed to Woking for cremation.

The New York Physicians' Mutual Aid Association.—At the annual meeting of this association, held January 26, 1898, the following officers were chosen for the ensuing year: President, Daniel Lewis; first vice-president, J. W. Hyde; second vice-president, W. F. Mittendorf; recording secretary, J. V. D. Young; treasurer, Robert Campbell. The report of the treasurer showed a permanent fund of $31,000, being an increase of $2100 during the year. The membership at present numbers 1451, showing an increase of 100 despite the numerous deaths during the past twelve months.

Houses of Ill-fame under the Guise of Massage Establishments.—This form of deception and vice has been carried on in London for a number of years. It is one of the most subtle, insinuating evils with which the detectives and police of that city have had to deal. The first suspicion that it had invaded our country and endeavored to establish itself here was aroused by the recent account of the case of a young girl from Buffalo, N. Y., who was lured from her home by an advertisement purporting to come from a massage establishment in New York City. On account of what she saw and the insults offered her in the house, she fled in terror, and later became insane.

The Dispensary Bill before the New York Legislature.—The bill of the Medical Society of the County of New York, recently introduced into the Legislature, has been advanced to its second reading. There is every prospect that it will pass the Legislature without serious opposition. The bill was not presented in the New York State Medical Society for endorsement, and no action upon this bill, was, therefore, taken by that society. It is reported, however, that the chairman of the new Legislative Committee of the State Society is strongly opposed to the measure. In consequence of which it would be wise for the friends of the bill to interview this gentleman promptly.

The New York State Board of Charities and the Dispensary Abuse.—The annual report of this organization recently presented to the Legislature urges that immediate steps be taken to stop the abuses of medical aid at the dispensaries, especially in New York City. The report estimates that 1,208,173 cases have been treated, and 1,938,637 prescriptions filled at the dispensaries of the Borough of Manhattan during the past year. The Board advances the idea that if one-half the thought and energy that are wasted in making the poor of our great cities dependent were used to encourage habits of industry and a spirit of independence, the condition of the destitute poor would be materially improved. New and larger buildings for Gouverneur, Harlem, and Fordham Hospitals are recommended.

The Medical Society of the County of New York and the Board of Health.—Representatives of the County Society appeared before the Board of Health, January 26th to present arguments in favor of restricting the powers of the latter organization. They contended that consumption should be removed from the list of contagious diseases, and the Board's power to sell vaccine and antitoxin should be taken away. Dr. Satterthwaite's antiquated argument that an effort which had been made in Naples over one hundred years ago to control and restrict the spread of consumption accomplished nothing, had little convincing effect. In regard to the manufacture and sale of antitoxin, President Straus of the Board of Health maintained that the only way to keep a good supply of antitoxin always on hand was to keep the laboratories in operation all the time. Consequently there must be a surplus, and it would be wasteful to throw this surplus away. The sale of it was a legitimate effort to reduce the expenses in the protection of the city against diphtheria and smallpox.

Discovery of an Agglutination Test in the Diagnosis of Yellow Fever.—The news comes from New Orleans that Drs. P. E. Archinard and R. S. Woodson of the United States Army have discovered an agglutination test to be used in the diagnosis of yellow fever. The test is made in the following manner: A drop of blood is taken from the lobe of the ear of the patient and dissolved in twenty times its volume of sterilized water. This is then placed in a culture-tube containing yellow-fever germs which have been active and increasing for twenty-four hours. In from five to thirty minutes after the drop of suspected blood dissolved in twenty times its volume is put into the culture-tube, the germs in the blood become agglutinated and motility ceases entirely, which shows that the blood is that of a yellow-fever patient. If, however, agglutination does not take place, yellow fever is not present. The yellow-fever germ has been found in between eighty-seven and ninety per cent. of the cases in which this test has been employed, therefore it must be superior to that of Sanarelli by means of which the germ was found in only forty-seven per cent. of the cases.

Special Meeting of the New York County Medical Society.—At a special meeting of this Society, held Monday evening, January 31st, the question whether it was advisable to prohibit or to license midwives was discussed in a general debate which continued for two hours. The general sentiment seemed to be in favor of abolishing such a guild as the midwives, but even those who most strongly favored this idea were quite positive in their opinions that such a measure could not be passed through the Legislature. Other speakers, and these formed no insignificant minority, were in favor of educating and improving midwives, and after submitting them to a course of study and examination to license them. This contention was based upon the statement that parturition is a physiologic process in the vast majority of cases, that only the services of a nurse or midwife are required, and that the class of people who employ midwives cannot afford the services of a physician. The second order of business was the resolution calling upon Dr. D. B. St. John Roosa to explain his recent public statements in the New York *Tribune* regarding the action of the Society and of its committee appointed to appear before the Board of Estimate and Apportionment in reference to granting public funds to private institutions. After various obstructive parliamentary proceedings, Dr. Roosa explained that his characterization of the action of the Society as a "snap vote" was in accordance with Webster's definition of the term, "as something done sharply, quickly, abruptly"; that in using the word, he had not intended to reflect disparagingly upon the action of the Society. In regard to his statement that the Committee knowingly disobeyed the instructions of the Society, this he believed to be true, assurance of which he had from two or three members of the Committee. As the meeting was a special one called for the purpose of discussing the bill concerning midwives and to listen to Dr. Roosa's explanation, no action could be taken. Dr. Roosa's explanation was received with attention and courtesy, and the meeting adjourned.

SPECIAL RESOLUTIONS.

RESOLUTIONS UNANIMOUSLY ADOPTED BY THE MEDICAL BOARD OF BELLEVUE HOSPITAL AT A REGULAR MEETING, FEBRUARY 1, 1898.

WHEREAS, in the opinion of this Board, the Health Department of New York has rendered great public service by the measures which it has taken to check the spread of infectious diseases, including tuberculosis, and by the zeal with which it has promoted scientific research, and

WHEREAS, there has been introduced in the State Senate a bill known as Senate Bill No. 5, which, if it becomes a law, will greatly restrict the field of work of the Health Department and hamper it in its efforts to secure improved sanitation for the citizens of New York, therefore, be it

Resolved, That this Board do humbly protest against Senate Bill No. 5, believing that its passage would work great injury to the interests of this community;

Resolved, That these resolutions be spread upon the minutes of this Board, and that copies be transmitted to the Senate Committee on Cities, to the New York City Health Department, and to the medical journals of this city.

OBITUARY.

THEOPHILUS PARVIN, A.M., M.D.

DR. THEOPHILUS PARVIN died at Philadelphia on the morning of January 29, 1898. He had been seriously ill for a month from cardiac asthma. Pulmonary edema, associated with renal complications, was the direct cause of his death. Dr. Parvin, whose life was devoted to the teaching of obstetrics and allied branches, at different periods of his career occupied chairs in the Ohio State Medical College at Cincinnati, in the University of Lowell, in the Indianapolis Medical College, and in the Jefferson Medical College, in which latter institution he was Professor of Obstetrics and Diseases of Women and Children at the time of his death. He was an honorary member of a number of Continental and British obstetrical societies, and has always been a prominent contributor to obstetric literature.

Dr. Parvin was born of American parentage at Buenos Ayres, Argentine Republic, in 1829, but from his earliest childhood the greater part of his life was spent in Philadelphia. He graduated from the Medical Department of the University of Pennsylvania in 1852, after having taken his arts' degree five years previously at the University of Indiana. As a mark of respect to Dr. Parvin, the lectures at the Jefferson Medical College were suspended on the day of his death, and resolutions of regret were passed by the trustees and faculty of the college, by the student body, and by the Theophilus Parvin Obstetrical Society.

CORRESPONDENCE.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

COMMON COUNCILS AND THE FILTRATION ORDINANCE—MORE RESIGNATIONS AT THE MEDICO-CHIRURGICAL COLLEGE—TO PROSECUTE INCOMPETENT DRUGGISTS—DELEGATION TO THE BOSTON CITY HOSPITAL—DR. WILLIAM PEPPER FOR MAYOR—GERMAN HOSPITAL—PHILADELPHIA NEUROLOGICAL SOCIETY.

PHILADELPHIA, January 29, 1898.

ANOTHER instance of the depraved personnel of the Common Councils of the City of Philadelphia is found in the action of that body of politicians in refusing a few days ago, in the face of the present disgraceful typhoid outbreak, to pass the popular loan-bill authorizing *water-filtration*—refusing, by fifty-three votes, to redeem themselves in the eyes of the public and to make what atonement lay in their power for the already large and wanton waste of human life which their past obstructionary tactics have caused. The fifty-three councilmen who succeeded in defeating the passage of the proposed filtration ordinance were the individuals who are now known

to favor the passage of another bill, now pending, forcing the city to purchase at a tremendous sum the rights of a private water-company; but the responsibility of more deaths from typhoid, due to their criminal delay, rests like a feather upon their shoulders in view of the individual enrichment to be derived from their support of this speculative syndicate's interests. The *Public Ledger*, a newspaper whose conservatism and reliability make its opinions authoritative, says editorially of this incident, that "nothing more infamous has occurred in the municipal history of Philadelphia," and directly charges the politicians referred to with a gross betrayal of trust, with an endeavor to squander public funds on useless purchases of water-rights, and with every moral responsibility for the delay in providing relief from the present epidemic. Charges of this kind from a newspaper like the *Ledger* are convincing, especially when the full names of the accused are printed along with the charge, as this paper has done. The scorn of the *Ledger* is echoed by every decent paper in the city, but they seem powerless, every one, to effect the slightest reform. Dr. A. C. Abbott, Director of the Bacteriological Laboratory of the Board of Health, after a thorough investigation of the epidemic, attributes the cause to infected drinking-water. The new cases of typhoid for the present week (January 29th) reach a total of 212. The deaths during the week numbered 10, or 13 less than last week. This makes a total of 1346 cases since the beginning of the epidemic last December, and of 887 cases during the first five weeks of this year. Meanwhile, the Board of Health remarks, in official notices, "Boil the drinking-water."

The *numerous resignations* which have been received of late from members of the faculty and board of trustees of the Medico-Chirurgical College were augmented a few days ago by the resignation of Mr. Charles W. Bergner, president of the board of trustees of this institution. Anent the latest change many spicy comments, *pro and con*, have been heard from those interested. Mr. Bergner states that his resignation was prompted by a change in the financial policy of the school, whereby it was proposed to guarantee to the professor of surgery, Dr. W. L. Rodman, a large yearly salary for a term of years. This change of policy he deemed unwise, inasmuch as to none of the other "practical" chairs are salaries attached, and he, therefore, sent in his resignation. The faculty have issued a public statement declaring that the situation was wholly misrepresented by the late president of the board of trustees, and further, a member of the faculty goes so far as to state without reserve that Mr. Bergner's resignation was requested in the interests of the school. Whatever the cause of the disagreement, the fact is apparent to the public, who have been acquainted for a week past with details galore of the fuss, that the ferment which they have scented points to a decided undercurrent of antagonism among a number of the authorities, lay and medical, of the college. To recapitulate, the "Medico-Chi." has within four weeks been deprived by resignation of the services of a professor of laryngology and dean, of a professor of obstetrics, of two trustees, and of a hospital superintendent. Truly, these are troublous times for this young institution, though it boasts of an appallingly costly operating arena, and of enormous State appropriations for its hospitals!

The State Pharmaceutical Board has determined to employ an agent to ferret out evidence leading to the *prosecution of violators of the pharmacy law* in this State, and it is said that especial attention will be directed to the incompetent compounding of physician's prescriptions by unqualified assistants. At the recent examinations held by the Board in this city, 134 candidates for licenses to practise pharmacy in Pennsylvania were examined, of whom but 39 passed. Of the 98 applicants for certificates as qualified assistants 42 were successful.

With the object of embodying in the additions to be made to the Municipal Hospital every modern facility of proven value, a delegation consisting of Dr. A. C. Abbott, director of the City Bacteriological Laboratory, Dr. Woodward of the Board of Health, Dr. W. M. Welch, physician in charge of the Municipal Hospital, and other city officials have gone to Boston, to make an *inspection of the Boston City Hospital*. The new building of this institution, which is considered one of the best equipped in America, will be studied by the delegation with a view of adopting its best features in the construction of the new wings to be added to the Philadelphia institution.

It is rumored that Dr. William Pepper will be presented as the next *candidate for the mayoralty of this city*. Dr. Pepper's public spirit and his wide interests in matters for the welfare of the community, together with his well-known executive ability, unite to qualify him for a public trust of this kind.

At a recent meeting of the board of trustees of the *German Hospital*, it was decided to divide the work of the institution into five departments. and the following were elected to assume charge: Chief of the medical department, Dr. James C. Wilson, with Drs. Harvey Shoemaker and Henry F. Page as assistants; chief of the surgical department, Dr. John B. Deaver, with Drs. George G. Ross and A. D. Whiting as assistants; chief of the ophthalmologic department, Dr. Charles Turnbull, with Drs. Edward K. Perrine and William T. Shoemaker as assistants; chief of the marine department, Dr. Fairfax Irwin, United States Marine Hospital Service; chief of the laryngological and aural department, Dr. Arthur A. Bliss. Dr. Adam Trau was elected consulting physician, and Dr. Carl Frese was re-elected medical superintendent.

At the last meeting of the Philadelphia Neurological Society, held January 24th, Dr. F. X. Dercum exhibited a case of *hemialgia* in a patient who for two years had had pain in increasing severity, first beginning in the right knee and at present involving the right lateral half of the body. The patient had been an iron worker, and said that for a number of years he was obliged to expose his right side to intense heat. There was also present tremor of both quadriceps extensors and the right gastrocnemius, and weakness of the right leg, together with some haziness of the optic discs, more marked on the right side. The disease was considered some anomalous lesion, probably of the basal ganglia. Dr. William Pepper, Jr., presented two specimens for Dr. Charles K. Mills, the first,

a brain showing *bilateral symmetric softening of the internal capsule*, from a patient of advanced years who presented symptoms of syncope and hemiplegia of the left, and later of the right side; the second specimen was a *cerebellar tumor* from a patient whose most prominent symptoms had been occipital headache, mental hebetude, and a staggering gait. Dr. Pepper presented for Dr. F. X. Dercum a specimen of *large cerebral abscess* of the superior parietal lobule, from a patient who had during life stupor, convulsions, right-sided hemiplegia, and intermittent high temperature ranges, but without ocular manifestations. Dr. J. W. McConnell reported a case of *neuritis of the fifth nerve*, which was followed by the development of herpes in this situation, and later by an eczematous eruption over the course of the nerve. The affection, which was of three-weeks' duration, was considered due to influenza. Dr. J. H. W. Rhein reported a case of *unilateral flushing and sweating of the face* in a young woman of hysteric tendency, in whom these phenomena were accompanied by swelling of the right arm, and by pain in the right hand and arm, probably induced by exertion. The following officers to serve for the present year were then elected: President, Dr. F. X. Dercum; vice-presidents, Drs. Wharton Sinkler and H. A. Hare; secretary, Dr. William G. Spiller; treasurer, Dr. Guy Hinsdale.

The total number of deaths reported in this city for the week ending January 29th was 458, a decrease of 3 from those of last week, and a decrease of 98 from the corresponding period of last year. Of the total, 143 were of children under five years of age. There were 121 new cases of diphtheria, with 28 deaths; 52 new cases of scarlet fever, with no deaths; and, as has been before noted, 212 new cases of enteric fever, with 10 deaths.

OUR BERLIN LETTER.

[From our Special Correspondent.]

REGULATION OF PRIVAT-DOCENTS, AND SCIENTIFIC FREEDOM AT THE GERMAN UNIVERSITIES—TREATMENT OF MIGRAINE BY THE VIBRATORY CHAIR—PROFESSOR STOHR AND THE MICROTOME DISEASE—THE VIRCHOW JUBILEE BANQUET.

BERLIN, January 27, 1898.

THE recent introduction of a bill in the German Reichstag *making the privat-docents responsible to the Ministry for their teachings*, instead of to the university faculties, as heretofore, is evidently going to cause a renewal of the storm of opposition which greeted a similar measure some time ago. Professors at the German universities owe their positions to government appointment, and receive their salaries practically as employees of the Educational Department of the Empire. They are responsible to the government, therefore, for their teachings, and may be readily "rounded up" if they, perchance, show a tendency to kick over the traces of what the Minister may consider conservative opinion in science and politics. Usually, however, by the time a man has become an ordinary professor at a German university he has either become so staid and conservative that disciplinary regulation is unnecessary or his work has made his position so assured that a certain liberty of thought is allowed.

It is quite different with the young privat-docents. They owe their positions to the faculty of the University, being qualified as private teachers by special examination. For their private opinions they are responsible to no one; for what they teach, only to the University faculty. In matters of theoretic opinion faculties are apt to be notably lenient in their judgment of teachers, especially in these later times, and so the privat-docents have become thorns in more than one minister's side. Some of them have dared to hold and publicly express social-democratic views—the term over here for certain very reprehensible opinions as to liberty and equality which are contained in our Declaration of Independence.

They have not taught such views because they are not teaching in departments in which it would be possible. Their example, however, cannot but be contagious, because some of their views have the unfortunate pervasiveness of truth. There are said to be especially two or three of the younger men in Berlin at whose heads the proposed regulations are aimed. One is teaching integral and differential calculus and units of measurement in electricity, and another histology—not very promising subjects when handled scientifically (and that the men in question are not scientific no one has even hinted), for the propaganda of social democracy. The serious thing is that these young men hold views which a paternal government considers subversive in tendency, and it wishes the right to dictate the opinions which shall obtain at the University, even outside of the class-room.

The protests against a previous measure of the same nature came from some of Germany's greatest teachers. Virchow pointed out that Germany owed her superiority in intellectual matters to the enthusiastic devotion of her young men to scientific pursuits. The privat-docents, entirely independent of authority in a way, but with a career to work out, have devoted themselves to purely scientific investigation and theoretic speculation in a manner which has brought out what was best in them. As a consequence the government has always had ready at hand plenteous elaborated material from which to select the members of university faculties. France and Italy have begun to realize that it is the lack of this body of free lances in science and philosophy which has kept the originality of their rising men in the background, and recent modifications of their existing educational institutions are along the lines of imitation of German university customs in the matter.

On the whole Virchow's plea for the present status—the freedom of privat-docents from government influence and from the thought of currying favor with ministers, is worthy of the man who in his own privat-docent days (they celebrated his jubilee last week) thought it advisable to accept a position away from Berlin at Würzburg because of the opposition aroused in government circles by some of his liberal views during the revolution of 1848. Notwithstanding government efforts and exaggerated tendencies toward paternalism, it seems probable that such views will prevail. After all, as has been pointed out,

their constitution provides for "freedom of scientific thought and teaching."

The situation of the matter here in Germany is not without its lesson for other countries, even for those in which there is no question of government interference. Too often the weight of influence of university trustees is thrown into the scale of a so-called conservatism that is sometimes a meddlesome opportunism. Recent events in university life in America point out that the precious heritage of free teaching in political science at least may be sadly encroached upon. Such an example is contagious, and one is apt to wonder if an overweening respect for tradition is to be the watchword in other sciences and what the results of such a policy would be. The protest on the part of universities here against the threatened encroachment on the liberty of teaching cannot but be re-echoed sympathetically by teachers all over the world and, as here, by none more cordially than by medical men who realize how much groundless authority and tradition may stand for.

At a recent meeting of the Berlin Medical Society, Dr. Ewer exhibited a model of a new apparatus, which its inventor calls a "Tremulor," *for the vibratory treatment of migraine.* It consists of a chair in which the patient sits while vibratory motions, rhythmic in character, are communicated to the body, especially to the head. It has been used with excellent results in a number of cases here in Berlin, and the apparatus has been found of use, too, in certain peripheral neuralgias in which the vibrations may be communicated to the affected nerve.

The theory of the curative effect of vibration would seem to be twofold: a tonic stimulation of nerve-endings and trunks by direct and reflex irritation, and a variation in the circulatory conditions which prevail in the part, with consequent changes in the nutritional metabolic processes. The invention would seem to be the application to separate parts of the body of Charcot's vibratory chair, which is still in use at the Salpétrière in the treatment of certain neuroses. Charcot took the hint for his invention from the number of neuralgic patients, who claimed that a ride on the railroad did them good. For many cases of paralysis agitans this is said to prove an excellent remedy for the feeling of intense constraint which accompanies the muscular rigidity that has of late years came to be pointed out as almost the most characteristic symptom of the disease.

Professor Stöhr has an article in the last number of the *Archives for Microscopical Anatomy*, which is interesting from several points of view. It is his first article since the acceptance of Kölliker's chair at Würzburg, and will, therefore, be followed with unusual interest by the many who have always looked for the contributions from the Anatomical Laboratory of the University of Würzburg as representing the forefront of progress in anatomic science. The article is in itself very striking, because it would seem to be a *demonstration of the falsity of the position still held by some histologists that it is from cells of epithelial origin that the lymphoid elements in the intestine come.* There would seem to be as little scientific probability of the cells of one special form of tissue ever changing into another as of finding one species of animal changing into another. Professor Stöhr's article would also seem to be a distinct contribution to the question of the origin of leucocytes—that interesting subject which underlies so much that is yet to be known of the physiologic properties of the blood, and a question which has become only more interesting as the battle of serum immunity and phagocytosis continues to attract so much attention.

At the end of the article are some striking remarks on the disease which causes so much dry rot among the pretty systems of the histologist and the pathologic anatomist—*the microtome disease.* The microtome has undoubtedly been the greatest discovery, next to the microscope itself, for microscopic science, but it has, in Professor Stöhr's words, "been the occasion of some of the most egregious errors, and has furnished seeming support to the most erroneous theories." It is extremely difficult in hardened and imbedded specimens to know exactly the positions which sections occupied *in vivo.* "Too often," to quote Professor Stöhr, "when it is fondly hoped that sections are perpendicular to a given plane, they are oblique or tangential." As sections are now cut extremely thin, countless false pictures are found, and selected ones from among them will furnish ample grounds for the support of almost any favorite theory which the investigator has started out to prove. The plea for greater openness to conviction on the part of scientific observers is evident, but men are only men, and error will creep in. The much more important reflection for the practical medical man would seem to be that pretty theories, even when founded on supposedly scientific data, require ample confirmation before they can be accepted as truth.

On Wednesday evening, December 29th, representatives from all the German universities greeted Professor Virchow at *the banquet held in honor of his jubilee as a teacher.* The grand old man of medicine received the ovation tendered him with a modesty all his own. For him there would seem to be but two things in his career which he looks back upon with personal gratification: One is that he has been able to accomplish something, though he insists himself, more by the direction he has given other's studies than by what he has done himself, in placing modern medicine on the secure foundation of a scientific pathology, and the other is that this work in pathology turned the attention of the medical world toward German medicine. Two talismans there were for him in his younger days—his country, his university. The felicitations extended so plentifully to him he insists on sharing with his German colleagues, and his toast is: "*Alma mater*, just about to enter upon the most glorious part of her history, in a new century, with the new clinics, museums, and laboratories which are already in course of erection for her."

Donation to the London Hospital.—The London Hospital has received an offer of $125,000 to defray the expense of a new out-patient department. The offer is accompanied by two conditions, *viz.*, (1) that the patients shall contribute a small sum toward the cost of medicines, and (2) that letters of admission shall be abolished.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninety-Second Annual Meeting, Held at Albany, N. Y., January 25, 26, and 27, 1898.

SECOND DAY—JANUARY 26TH.

MORNING SESSION.

(Continued from page 160.)

DR. E. F. BRUSH of Westchester County read a paper, entitled

THE IMPORTANCE OF THE HYGIENIC MANAGEMENT OF DAIRIES

(which will appear in a future issue of the MEDICAL NEWS).

DR. W. H. HEATH of Erie County then read a paper on

THE MUNICIPAL CONTROL OF THE MILK-SUPPLY IN CITIES AND VILLAGES.

The author brought out the fact that although milkmen in cities are obliged to obtain a license to sell milk nothing of the kind is required of dairymen. The State Board of Health is wofully negligent in this respect. A high standard should be adopted, and sustained by stringent rules enforced by the State. Infected milk from diseased animals should be guarded against by veterinary examination of the herds at regular intervals. Contamination after milking should be prevented by absolute cleanliness of the dairy. Dairy inspection should be enforced, particularly with regard to the following points: (1) Character of the herds, as to breed, health, and whether or not subjected to veterinary examination; (2) method of cleansing utensils, and the length of time devoted to cooling of the milk—an important point; (3) water-supply; (4) character of the employees.

A milk-house should be sufficiently large and constructed of such material that it can be flushed and cleansed. There should be no communication with stable, living-room, or water-closet. The storage and cooling-room should be scrupulously clean, should open to the outer air, and should not have any sewer or drain connection. Rules containing explicit directions as to the cleansing of cans, utensils, etc., should be adopted, and conspicuously posted in the milk-room. Cans should bear tags on which is marked the date and hour of milking, and no milk should be sold which is more than twenty-four hours old. No disinfectants should be used in a dairy. Any dairyman who does not conduct his dairy on these lines should be deprived of his license.

DR. HERMAN E. HAYD of Erie County read a paper, entitled

SOME POINTS IN THE TECHNIC OF THE ALEXANDER OPERATION.

The author advocates the operation in which the ligament is picked up at the external ring, and lays particular stress upon the necessity of saving the knuckle of fat which appears at the external opening, as he considers this an important landmark. He then cuts off the ends of the ligament and transfixes the cord through a thick portion of the muscle, taking care not to draw the suture too tightly in approximating the pillars, believing that too much stricture upon the poorly nourished cord is apt to favor suppuration. He deprecates all operations which open the canal, as he is convinced that such a course is unnecessary, complicates the procedure, and favors the production of hernia.

DR. EDWIN B. CRAGIN of New York County read a paper on

THE PRESENT STATUS OF VAGINAL OPERATIONS FOR DISEASES OF THE PELVIC ORGANS. (See MEDICAL NEWS, January 29, 1898.)

DR. W. E. FORD of Oneida County read a paper, entitled

THE REMOTE CONSEQUENCES OF EXCESSIVE UTERINE HEMORRHAGE.

Sudden losses of blood of considerable amount are not especially dangerous. In these cases the blood-count shows great diminution of red cells, two million or even less to the cubic millimeter, but restoration to the normal five million speedily occurs. Shock seems to be in proportion to the diminution in the number of red cells. After childbirth the blood-count does not show much change from the normal, but when a laceration occurs which extends above the internal os the loss of blood is likely to be large during the labor and to continue afterward. The degeneration of the endometrium in these cases often protracts the hemorrhage. As a result of the constant leaking of blood, the local degeneration gives rise to a neurosis which results in a painful and sensitive uterus. This state is followed by neurasthenia in many instances, even though there has been little inflammatory trouble. These are the cases in which ordinary trachelorrhaphy fails to cure the nervous symptoms. Amputation of the cervix is a better operation in these cases. Small lacerations not extending above the interal os often require no treatment whatever, but if inflammation be present cicatrization surely follows, then curetting combined with ordinary trachelorrhaphy is necessary to cure the patient. In these last-mentioned types nervous symptoms are not usually presented, which is due, as the author believes, to the fact that there has been less loss of blood. A study of a large number of cases in which nervous symptoms were prominent leads to the belief that persistent hemorrhage only precedes menorrhagia. Nervous symptoms should not be attributed to reflex conditions. The blood-count in most of these cases, even when the patient is pale, thin, and nervous, shows that there is no true anemia; a record of blood-counts in several cases showed that only rarely does the number of red cells fall below 4,500,000 and the amount of hemoglobin below eighty-five per cent. Women with bleeding fibroids and cancer of the uterus present true secondary anemia, and nervous symptoms in such cases are not nearly as frequent or severe as in cases in which there has been continuous hemorrhage from high tears. The reason why so many women apply for treatment of lacerations several years after childbirth is that true neuralgia is an

ultimate result of continuous degeneration, thus differing from the processes of inflammation which manifest their results much sooner. Hence, hemorrhage ought to receive more consideration and pure inflammations less in estimating the causes which produce neurasthenia uteri. All tears which open the internal os should be repaired before the neuralgic condition results. Too much should not be promised in long-standing cases from simple trachelorrhaphy. Microscopic studies of the blood show why iron tonics do not relieve the nervous symptoms of women having high cervical tears. The author then contrasted the blood-counts in these cases with those of an entirely different class of patients—young women with delayed or suppressed menstruation. In these latter iron is of little value, and in such a blood-count shows that real anemia does not exist.

Dr. J. Riddle Goffe of New York County then read a paper, entitled

THE ANATOMY AND FUNCTION OF THE PELVIC FLOOR IN WOMEN, AND THE OPERATION FOR REPAIR OF INJURIES DUE TO PARTURITION

(which will appear in a later issue of the Medical News).

DISCUSSION.

Dr. George M. Edebohls of New York County: It is a matter of congratulation to me to hear those who are familiar with Alexander's operation commend it so highly. It has always seemed to me irrational to open a woman's abdomen and create adhesions in cases of movable retroversion, and I am glad that the still small voice of conscience is making itself heard, and that operators have begun to consider it almost criminal to open the pelvic cavity, either from above or below, for this purpose. Alexander's operation will accomplish all that is necessary in these cases. I know of no one who performs the operation better than Dr. Kellogg of Battle Creek, Mich., who fastens the ligaments to the fascia. The only objection to his method is that the ligaments are placed in an unnatural position. The operation as performed by Dr. Hayd is the old operation of picking up the ligament at the external ring where it is weak and apt to tear as it is pulled out. Within the canal it is well developed. There is no danger of the ligament parting if the canal is opened before the ligament is picked up. This may be objected to as tending to weaken the inguinal canal, but such is not the case if the wound is closed by the Bassini method.

Dr. W. Gill Wylie of New York County: I agree with the last speaker that in simple cases Alexander's operation is an ideal one and much to be preferred to that in which the uterus is attached to the abdominal wall—a method that is somewhat obselete. I think, however, that Alexander's operation should only be performed by men skilful enough to be able to do it without opening the inguinal canal.

In regard to Dr. Cragin's paper, I think the status of the vaginal operation is now fixed. Nowadays, everyone does vaginal work, and only time will tell whether the vaginal is to be preferred to the abdominal route. Both methods are equally good in the hands of the expert, and the death-rate is not greater in one than in the other. In regard to the comparative value of ligatures and clamps, good results may be obtained by the use of either. Personally, I prefer the clamps. I now use them altogether, employing five or six pairs, because I think they leave the vagina in a better condition than when ligatures are employed. There is not that shortening of the vagina which sometimes follows the use of ligatures.

I was much interested in the paper of Dr. Goffe on the perineum, although I cannot agree with him in regard to the function of the transversus perinei muscle. My idea is that it is a very active muscle, and that it retracts and everts the mouth of the vagina when the perineum is lacerated. It is because the general surgeon does not understand the action of this muscle that he sews up a perineum improperly. As described by Dr. Goffe, I should think that a good deal of this everted tissue would be included in the stitches, and a bad result follow.

Dr. Albert Vander Veer of Albany County: I believe it is the consensus of opinion that Alexander's operation is indicated in cases of retroversion in which the uterus is movable. The suggestions of Dr. Hayd are worthy of careful consideration. I think, however, that the operation is performed in many cases in which it is not required. It may be avoided by palliative treatment, and by having the patient systematically assume the knee-chest position.

In regard to Dr. Cragin's paper, I think that the operator who is not familiar with vaginal work had better turn his attention to something besides surgery. I was one of the first to do the vaginal operation; eighteen years ago I removed a fibroid tumor through the vagina. The cases should, however, be carefully selected, and the position of the appendages ascertained before making the vaginal incision.

Dr. Ford's paper is one which goes home to the average practitioner. Many of the patients to whom he referred may be relieved by a proper line of treatment, and let me say right here that a great deal of benefit may be derived by these patients from the use of the bicycle. When trachelorrhaphy is indicated, all the hard cicatricial tissue in the angles of the tear should be removed as pointed out by Dr. Emmet.

Dr. Goffe's paper deals with the old muscle over which we have struggled many years. He has brought it out very clearly by his illustrations on the blackboard, and in a manner which must impress the obstetrician with its importance.

Dr. Ford: In regard to Dr. Goffe's operation, I have been employing a method in which the silver wire sutures are passed, *not* through the mucous membrane, but about a quarter of an inch within the denuded surface, a deep bite being taken by the needle before it is brought out on the opposite side, and making a figure-of-eight as it is crossed there, pulling up the perineum to its normal position.

Dr. George M. Edebohls of New York County then read a paper, entitled

INVESTIGATION AND EXPLORATION OF THE OTHER KIDNEY IN CONTEMPLATED NEPHRECTOMY.

A knowledge of the presence and condition of the other kidney is of the first importance when nephrectomy is contemplated; inasmuch as there are cases on record in which autopsy proved that the kidney removed was the only one present. Palpation will usually determine the existence of the kidneys, although an enlarged gall-bladder has been known to be mistaken for the right kidney. It is difficult, however, to ascertain the condition of the kidney by palpation alone. Cystoscopy and catheterization of the ureters are of great value in this respect, although not always entirely satisfactory, nor should the danger of carrying infection to a healthy kidney be forgotten. Collecting separately the urine of each kidney will often throw light upon the condition. As a final resort, incision down upon, and exploration of, the opposite kidney may be performed before completing a nephrectomy. This procedure was first practised by the author in 1894, and he has employed it in two additional cases since that time.

DISCUSSION.

DR. WILLY MEYER of New York County: I think Dr. Edebohls' paper is of immense importance. A surgeon cannot feel easy when he removes a kidney unless he knows that the remaining organ is healthy, and every method must be employed to determine this point. In these cases cystoscopy and ureteral catherization should be employed. If the mouth of one of the ureters is found to be ulcerated, its kidney is probably diseased and the other healthy; for I am convinced that as a rule inflammatory conditions and tuberculous disease are ascending and not descending. Should these means fail, I recommend suprapubic cystotomy and direct ocular inspection of the bladder with the patient in the Trendelenburg posture. The ureters may also be catheterized at this time, the catheters being left *in situ* twenty-four hours, if necessary, to determine if both kidneys secrete healthy urine.

DR. P. M. WISE, of Albany County read a paper, entitled

THE PAST, PRESENT, AND PROSPECTIVE METHODS OF TREATMENT OF INSANITY IN THE STATE OF NEW YORK.

After briefly reviewing the treatment of insanity in the past, the author criticized the lack of instruction in the medical schools on the subject, and stated: "At the present time, when one of every two hundred of the population is insane, and the insane diathesis so permeates society that we dare not estimate its extent numerically, the schools dismiss the subject in almost a flippant manner." He referred to the small interest taken by physicians throughout the State in the hospitals maintained by the latter. State care means a uniform standard of care and treatment for those requiring segregation, and 19,000 of the 21,000 insane are at present properly domiciled. In two years, if the present policy be supported by the Legislature, all insane persons will be provided for. The foremost object of this great State charity is the restoration of the insane to health, and during the past year 1800 insane patients under State charge have been discharged in a condition to be useful. If the incurable forms of insanity were deducted from original admissions, sixty per cent. of the remainder would be shown to have recovered.

The author maintained that the present practice in the standard hospitals was abreast of medical progress, and that the changed condition for the better in asylums was due to rational methods of treatment, and not to suppression, as formerly. He called the attention of physicians to the dangers of narcotism in the early treatment of the insane, and said that the preservation of household quiet had resulted in disaster. The removal of mind-poisons was dwelt upon as well as the toxic effect of sense-irritation upon the excited brain. The present principles of treatment in hospitals are founded upon the removal of active causes—toxins, irritation of the nervous mechanism from all sources, and the improvement of the general health. The governmental policy is based upon the truism that every patient cured relieves the State from maintaining one person for a period of twelve years, which is the average duration of insane life. He referred to the unfavorable character of the cases now admitted, and also to the fact that the expectancy of curability is decreasing. The over-worked, over-stimulated, over-fed, immoral, and misguided are in greater excess than formerly. Resistance is weakened through heredity, and the weapons of attack are increasing. The cooperative plan has been adopted in the State Hospital for the Insane, and an experience gained at one State institution is available to all. This is shown in the pathologic work which is united for all the hospitals, and this plan has met such general favor that it is being followed by other States and foreign countries. He predicted marked advances in pathology as a result of recent technical methods which permit examination nearer the border-line of health and disease. Toward the consummation of this result the hospital system for the insane is working. He referred to the advantage enjoyed by the general physician in observing cases in the earliest stages, and to the relation of the physician to the prevention of insanity. Upon him must depend almost wholly whatever checks are exercised by society in the present almost universal destruction of nervous energy and resistance.

DISCUSSION.

DR. LANDON CARTER GRAY of New York County: I have been very much interested in this paper, and think we may all agree with the author in believing that the treatment of the insane in the State hospitals has undergone a very great improvement, and that an intelligent effort is being made to do what is best; still (in a spirit of meditation and not of criticism), I would like to have Dr. Wise's opinion of certain inherent defects in the present system. In the first place, it is a significant fact that in spite of the millions which have been annually spent upon these State institutions in the State of New York, not a single text-book, not a single new discovery in pathology, not a single new demarcation of symptoms, and nothing new in therapeutics has come from any man connected with them. This must be due to an inherent defect in the State care of the insane. If you or I want to study something in medicine or surgery we visit a medical center, go to hospitals, begin at the bottom of the lad-

der, wash sponges for six months, and at the end of that time we have charge of fifty or sixty patients, although still not in charge of them, for there is a visiting physician who comes in every day and directs the treatment; but we live in an atmosphere of medical teaching, therefore we learn. Precisely the reverse of this state of affairs is found in the case of the study of insanity. The men who receive appointments to insane asylums did not formerly have to pass a competitive examination, although I am happy to say that such is now necessary. They do not live in a medical center. They are isolated, and live in what is practically a large insane boarding-house, away from the clash of intellect which makes the mind keen and the man ambitious. Therefore, it seems to me that the system is defective. I am no reformer, and I do not know how the difficulty can be remedied. A gentleman who is in a position such as that held by Dr. Wise should use his efforts to change all this. What is done with the great wealth of clinical material? It should be the duty of the State to supply every clinic within its territory with the material required. It is the duty of the State to encourage and make easy the visiting of competent men who wish to study neurology and psychology. So far, knowledge of these subjects has been largely anatomic and pathologic. It is just beginning to be understood clinically, and it is very important that this knowledge should be extended.

Dr. Wise: I will admit that some of the criticisms made by the last speaker have a substantial basis. It cannot be denied that the hospitals of this State are defective in many respects. I very much deprecate the fact that nothing new in therapeutics has emanated from these institutions, and yet whatever additions we have had to psychiatrics has resulted from the work of persons connected with such institutions. The tendencies are certainly in the right direction, and steady progress would be secured by the hearty cooperation of the workers outside the institutions. The insane hospitals are isolated, it is true, but this is from necessity; and yet I believe that the material which is in these hospitals should be used in teaching. Insane asylums have only just emerged from municipal control, and I think that sooner or later the efforts of the Lunacy Commission will result in permitting this material to be used in medical schools.

Afternoon Session.

Dr. Herman Mynter of Erie County read a paper, entitled

A YEAR'S WORK IN APPENDICITIS.

The author said he considered all classifications of appendicitis artificial, but, for clinical purposes, he divides the affection into simple catarrhal appendicitis, ulcerative appendicitis, with or without perforation, and septic appendicitis, with or without abscess. More deaths occur as a result of appendicitis than from any other abdominal disease. The prognosis is unfavorable when medical treatment is employed, the death-rate being between 16 and 20 per cent. Of those patients treated medically who recover, 50 per cent. suffer relapses. The mortality in those cases in which treatment is surgical depends upon whether or not the operation is performed at an early stage.

Dr. A. M. Phelps, of New York County then read a paper on

CONGENITAL DISLOCATION OF THE SHOULDER BACKWARD, WITH A REPORT OF SEVEN CASES AND AN OPERATION FOR ITS RELIEF.

The first case of this kind which was seen by the author was brought to him in April, 1895, at which time only six similar cases had been recorded. Such cases are generally supposed to be instances of unrecognized dislocation existing from birth. The author discovered not only dislocation but fracture of the glenoid in five of his cases, and believes the injury is directly due to traumatism inflicted by the accoucheur at the time of birth. In but one other case had operative treatment been employed before the author's first operation was reported. Operation was performed in all of his cases save two; in one, that of a child nine weeks old, he was able to reduce the dislocation without opening the joint, and a second refused operation. In the remaining five cases the joint was opened by incision, the dislocation reduced, and the head of the bone excised in order to make allowance for the shortening of the muscles due to the long-standing dislocation. The retaining capsule was then cut away, a drainage-tube inserted, and the wound closed. A slight paralysis will remain on account of injury received by the nerve from the same violence which preduced the dislocation. When the joint alone is injured, the results are fairly good, although motion is always slightly limited. The arm should be put up in a rotated position.

DISCUSSION.

Dr. Lewis A. Weigel of Monroe County: This subject is very important to the general practitioner and obstetrician, for there is no doubt that the condition in question is very often unrecognized. Within the past two weeks I have seen three cases of so-called "obstetric paralysis," and in two of them I am sure there is a dislocation: for the palm of the hand points backward—a diagnostic sign of this condition. I am prepared to endorse the author's statement that in nearly every case the injury is due to violence inflicted at birth. It is also my opinion that in some cases the paralysis is due to injury to the central nervous system at this time. In these cases there is always presented a history of difficult labor, long compression of the head followed by difficult delivery of the shoulders. In one of the cases which I recently saw there was asymmetry of the face, which would indicate central injury.

The author has referred to shortening of the arm as a result of the dislocation proper. It seems to me that it is posstble that in a certain number of cases this shortening is due to arrested growth and atrophic change. I believe also that the paralysis is due to injury to the nerve. Before subjecting patients having this condition to operation, an accurate knowledge of the condition should be obtained by means of fluoroscopic examination and X-ray photographs.

Dr. Phelps: Regardless of whether paralysis exists

in a given case I would invariably reduce the dislocation, for this is the only means of placing the muscles in their normal position. In regard to the etiology, I think there can be no doubt that the condition is due to violence on the part of the accoucheur. In the cases I have operated upon I have found evidence of fracture, fragments being detected in three of them.

DR. REGINALD H. SAYRE of New York County then read a paper, entitled

THE TREATMENT OF RACHITIC DEFORMITIES.

The author advocated the early treatment of the rachitic condition in order to prevent deformities. The etiology of the disease is not well understood. It generally develops shortly after birth, and is supposed to be due to dietetic and hygienic factors. There is also some hereditary tendency which causes the disease to develop in some children and not in others. There are decided changes in the long bones, which become soft and flexible. Later, they become extremely hard. "Pigeon-toeing" is a conservative effort on the part of a child who is rachitic, because it finds that it can best support the weight of its body by turning in the toes. This should not be corrected, for it will take care of itself when the general condition is improved by proper diet, hygienic surroundings, and constitutional treatment. Cod-liver oil is excellent. Phosphorus has also been recommended, but the author has not seen good results follow its administration. If patients are seen early and treated in this way, but slight deformity will result. When the bones are markedly soft, the child should not be allowed to stand on its feet. In the case of an infant it should be placed in a wire basket or upon a padded board. The legs of older children should be put up in plaster of Paris, which is better than any apparatus. When seen in a late stage, after the bones have become hard, the deformity must be corrected by breaking or cutting the bone and putting the limb in a plaster-cast.

DISCUSSION ON THE MANAGEMENT OF HYPERTROPHY OF THE PROSTATE GLAND AND ITS COMPLICATIONS.

DR. L. BOLTON BANGS of New York County, opened the discussion with a paper, entitled

GENERAL CONSIDERATIONS AND CATHETER LIFE

(which will appear in a later issue of the MEDICAL NEWS).

DR. SAMUEL ALEXANDER of New York then read a paper, entitled

PROSTATECTOMY AND PROSTATOTOMY, SUPRAPUBIC AND PERINEAL,

in which he gave the results obtained in 205 operations. The author stated that in the majority of cases of hypertrophy of the prostate, operation is not required, palliative treatment being all that is necessary. The value of regular catheterization cannot be over-estimated, and too little attention is given to instructing the patient how the catheter should be used. In those cases in which the catheter fails to give relief, owing to the shape or size of the enlarged prostate, operation should be performed; but catheterization should be employed in every instance until it fails. Operation is indicated (1) when spontaneous urination is impossible, (2) when there is marked and constant vesical irritation, (3) when the amount of residual urine is steadily and surely increasing, (4) when catheterization is becoming more and more difficult, (5) when catheterization is followed by severe cystitis, (6) in cases of cystitis which resist all treatment, and (7) when the patient refuses to use the catheter. The author prefers the suprapubic operation as giving better results in regard to reestablishing voluntary urination. The death-rate is also less than that which follows the perineal operation. When drainage is required, the latter operation is the better. The condition of the kidneys at the time of operation should always be ascertained, as this is a most important factor in determining the result. The entire obstruction should be removed or failure will be sure to follow. Cystitis is not a contraindication to the operation.

DR. WILLY MEYER of New York County continued the discussion with a paper, entitled

BOTTINI'S GALVANOCAUSTIC RADICAL TREATMENT, AND THE PALLIATIVE TREATMENT OF HYPERTROPHY OF THE PROSTATE.

The author advocated the use of this method in the conservative treatment of the condition in question before operation is resorted to. He exhibited the instrument, which consists of a hollow metal catheter in which is hidden a small platinum knife which is made to emerge by the turning of a screw placed at the lower end of the instrument. A scale on the handle also shows the extent of the cutting surface exposed. The amount of current employed to heat the knife is regulated by a rheostat. The technic is simple. The bladder is first completely emptied. If irritation be present, the urethra is cocainized. The current is turned on before the instrument is inserted. Two or three grooves are made at the site of the enlargement of the prostate. The author has employed the method three times with good results. The cases, however, must be carefully selected.

DR. L. S. PILCHER of Kings County read a paper, entitled

CASTRATION FOR THE RELIEF OF HYPERTROPHIED PROSTATE,

in which he recommended the employment of this procedure in place of prostatectomy or prostatotomy. It requires no special skill and gives most satisfactory results.

DR. E. L. KEYES of New York County read a paper on

STONE ASSOCIATED WITH HYPERTROPHY OF THE PROSTATE.

The author alluded to the fact that in a discussion before the Society six years ago he advocated litholapaxy whenever practicable, whether or not the prostate be enlarged. He had then stated his belief that even in the case of a very small stone, when the prostatic condition is a main factor in the general morbid state, that it might be wise to insist on suprapubic lithotomy in order that partial prostatectomy might be performed—the patient's necessity being converted into the surgeon's opportunity—

and this opinion, which he still holds as a result of growing experience, is based upon the following facts: (1) lithotrity is a maneuver of the specialist. A general surgeon will perform lithotomy, cystotomy, or prostatectomy as well as, and often better, than a genito-urinary specialist. This is not so in the case of litholapaxy, which, therefore, can never become a general operation; (2) even the expert lithotritist cannot, for mechanical reasons, remove every fragment or grasp a final flat piece of stone from the deep *bas fond* in some cases of enlarged prostate. Even if he could, such removal would not and does not relieve the subjective symptoms, but rather aggravates them in some instances; (3) even suprapubic lithotomy, in which the entire stone is removed, does not *necessarily* relieve the symptoms, although it usually does so in great part. Suprapubic lithotomy *plus* partial prostatectomy does not *necessarily* relieve unless the vesicle orifice of the urethra be lowered and all bar-like obstructions removed.

The author stated that in France the Guyon school is returning to an advocacy of catheter-life, and is not advising prostatectomy. The operation is too severe to be generally advocated. Vasectomy is not at all reliable. Castration has been much overdone, and is not so devoid of risk to the patient's body and danger to his mind as might at first appear. Bottini's operation has not yet been tested and cannot be pronounced upon.

The following conclusions were reached: (1) When stone complicates enlarged prostate, if the condition of the latter be such that were the stone absent no operation would be called for, the question is to be solved by deciding whether the obstructive quality of the prostatic enlargement, the size of the bar, the depth of the *bas fond*, the irritability of the prostatic urethra and its resentment of instrumental interference, are sufficient to make litholapaxy impossible or to make it possible only at the expense of leaving the patient worse off than before. If such conditions obtain the stone should be removed by the knife. (2) In short, the question is one of diagnosis by the searcher, the cystoscope, rectal touch, and the tentative testing of the prostatic urethra with instruments. (3) The mere size of the prostate is not a factor in the problem. (4) The size or position of the stone is not a factor, except in the case of encysted stone, or one too large to be grasped by the lithotrite, or in the case of a foreign body. The size of the stone alone is relatively an argument against litholapaxy, since the symptoms in such a condition must be ascribed rather to the prostate than to the foreign body. (5) If lithotomy be performed, the suprapubic route is to be preferred, since this opens the door for more perfect work, and allows the surgeon to remove obstructions such as the third lobe, interstitial growths, outstanding horse-collar enlargements, bar, and to *lower the vesicle end* of the urethral floor, thus accomplishing all that could be done by a more extensive prostatectomy without very seriously increasing the operative risk. (6) Finally, here as elsewhere in surgery, the only safe, practical guide is surgical judgment based upon diagnosis guided by experience.

DISCUSSION.

DR. PILCHER: The presentation of the subject and the conclusions arrived at have been given in a masterly manner by Dr. Keyes which must commend them to our judgment. I have traveled over the same road and have come to the same conclusions—we must resort in some cases to suprapubic cystotomy for the removal of the obstruction to urination. It is the extreme danger which follows this bloody interference with the prostate when the bladder is opened which has caused me to advocate removal of the testicles, although I appreciate the enormous objection which may be raised against this procedure. I think, however, that this objection is exaggerated, and can be obviated altogether. I am not a partisan of any one method, and have merely contributed my own personal experience.

EVENING SESSION.

ANNIVERSARY ADDRESS BY THE PRESIDENT.

THE OBLIGATIONS OF THE PHYSICIAN AND THE LAYMAN TO EACH OTHER.

"There is a general tendency affecting all grades of people toward that which will create a sensation, and the advancement of science having disturbed very materially our old creeds, we have been disposed to accept those which seem newer and which seem akin to the marvelous. This is evidenced by the success of the traveling doctor who goes from place to place, heralded by posters and trumpets, and who cries his wares and his miraculous cures from the house-tops. The old-time doctor is passing away, and in his place we have the up-to-date medical man who, having imbibed his share of the spirit of the times, is losing in many respects more than he gains. It is his work which has reduced the death-rate in our largest cities to the lowest point in the history of the land, and which has built up the magnificent fortunes of life-insurance institutions.

"There is an unidentified something in the make-up of the medical man which you do not find in any other citizen. I speak of that jealousy which exists between himself and his brother practitioner, which makes him give free medical attendance to a patient who is not able to pay the fee demanded by him, but who is able to pay a smaller fee to his less successful brother. I doubt very much if any legal act could be devised to meet such emergencies, but if the members of the medical profession would respect the rights and privileges of each and every individual of their august body, and would see to it that no act of theirs would tend to jeopardize the interest of another, then would come the solution of this entire difficulty without the intervention of law.

"I am not a believer in reducing the practice of medicine to the status of a trade. I do not believe that the profession should organize itself into a trade's union for the furtherance of the interests of its members professionally, politically, and financially; but I do believe that there should be that honesty and respect for others' rights which should make men realize the justice or injustice which has been dispensed to their predecessors before serving in the capacity of successors. My special point is, that if we do not sustain honorable members in their expectation of just and courteous treatment we injure and degrade the profession itself."

THIRD DAY—JANUARY 27TH.

MORNING SESSION.

The Committee on Nominations announced the following committees:

Committee on Arrangements: Samuel B. Ward of Albany, Reynold W. Wilcox of New York, W. J. Nellis of Albany.

Committee on By-laws: H. D. Wey of Elmira, Nathan Jacobson of Syracuse, F. C. Curtis of Albany.

Committee on Prize Essay: Joshua M. Van Cott of Brooklyn, Andrew McFarlane of Albany, George McNaughton of Brooklyn, W. S. Cheesman of Auburn.

Committee on Publication: F. G. Curtis of Albany, Daniel Lewis of New York, C. H. Porter of Albany, W. W. Potter of Syracuse.

Committee on Hygiene: Henry R. Hopkins of Buffalo, A. H. Bartley of Brooklyn, C. E. Bruce of New York, J. M. Mosher of Oneonta, H. F. Hart of Shrub Oak, George Seymour of Utica.

Committee on Legislation: Frank Van Fleet of New York, Arthur G. Root of Albany, Eugene Wende of Buffalo.

Committee on Ethics: Evarts M. Morrell of Yonkers, George McNaughton of Brooklyn, Lewis A. Weigel of Rochester.

State Board of Examiners: Eugene Beach of Gloversville, H. D. Wey of Elmira, J. P. Creveling of Auburn, Daniel Lewis of New York.

DR. T. D. CROTHERS of Hartford, Conn., read a paper on the

TREATMENT OF DELIRIUM TREMENS,

in which he stated that the condition is due to alcoholic injury to the brain-centers, in some cases to the action of bacteria, and to auto-intoxication from various constitutional diseases. The principal indication in treatment is the induction of sleep. The use of strong opiates and hypnotics, especially chloral, are to be deprecated on account of the depressant after effects. The use of alcohol should be at once stopped, in spite of the widespread belief that its immediate withdrawal will cause death in some instances. Many of the cardiac stimulants are dangerous, and it is best to avoid their use. Elimination is of first importance. To favor this the hot bath is most essential. In private practice a blanket sweat will answer the purpose, and free diaphoresis should be kept up for two or three days. The employment of diaphoretic drugs should never be substituted for external applications. Calomel, followed by salines, should be administered. If restraint is necessary, it should be mild and alternated with liberty in order that the muscular excitement may be worked off. But little food should be given until the period of sleep comes on. The classic delirium tremens of the text-books is rarely seen. The old writers do not mention the dementia and melancholia which often follow the continued use of alcohol. A new chapter should be written on the pathology and treatment of this form of delirium. The large number of deaths which annually occur in police stations among persons who are found comatose on the street, is due to ignorance in caring for them.

DR. H. S. DRAYTON of New York County then read a paper, entitled

INTRATRACHEAL INJECTIONS IN DISEASES OF THE BRONCHIAL TUBES AND LUNGS.

This mode of treatment was first suggested in 1840 by Dr. Horace Green of New York, and elicited much adverse criticism at that time, the method being denounced as cruel. Later experiments have shown that the pulmonary mucous membrane is capable of absorbing liquids without irritation and without interference with respiration. The difficulty of manipulating the instruments is overcome by good illumination, a knowledge of the laryngeal region, a steady hand, and practice. A syringe holding half an ounce, devised by Dr. Joseph Muer of New York, is employed, to which is attached a curved metal tube about six inches long. If there is irritability of the throat, a spray of cocain may be first used, but this is rarely necessary. The syringe having been charged, the patient is instructed to sit upright and grasp the tongue with the right hand, drawing it well forward, at the same time opening the mouth wide and throwing back the head. The tube is then introduced and the injection made. This is more easily done with the aid of the mirror. Three injections of one dram each are given at a sitting, such material being used as will act adversely on the bacteria and produce a soothing effect as well as a mild stimulation; for instance, olive oil, glycerin, methol, eucalyptol, camphor, etc.

In the absence of the retiring President, the Vice-president introduced the newly elected President, Dr. John O. Roe.

Upon taking the Chair, DR. ROE said: "Ever since I was first sent as a delegate to a meeting of this Society, nearly twenty years ago, it has been my privilege to attend its annual meetings, and the profit which I have acquired in so doing I hope I may be able to return to the general stock of its medical knowledge. I will endeavor to show my appreciation of the preferment shown me by my zeal in the future, and, with your assistance, I will hope to make the next meeting as successful as those of the past. I thank you cordially for the honor conferred upon me, and wish you all a year of health, happiness, and prosperity."

The meeting was then declared adjourned.

THERAPEUTIC HINTS.

For Blepharitis Marginalis.—

℞ Ichthyol . . . . . *m.* xiv
Ung. zinci oxidi . . . . . ʒ ss.

M. Ft. ung. Sig. Apply to corners of closed eyelids.

For Pulmonary Edema in Children it is recommended to give one to three drops of the tincture of strophanthus every three hours. Diuresis is produced and the edema is quickly diminished.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXII. NEW YORK, SATURDAY, FEBRUARY 12, 1898. NO. 7.

ORIGINAL ARTICLES.

CATHETER LIFE, AND SOME REMARKS ON THE ETIOLOGY OF HYPERTROPHY OF THE PROSTATE GLAND.[1]

BY L. BOLTON BANGS, M.D.,
OF NEW YORK;
CONSULTING SURGEON TO ST. LUKE'S HOSPITAL, ETC.

SIR HENRY THOMPSON states that an enlargement of the prostate gland of moderate degree occurs in one out of every three males who reach middle age; (2) that twenty per cent. of all men have fibrous tumors of the prostate previous to the fiftieth year of life; (3) that after the age of fifty years one man in every eight has marked enlargement of this gland, and finally (4), that the disease rarely begins later than the seventy-fifth year of life. Reginald Harrison states that one-third of the male population of the world who have passed the age of fifty-five years are the subjects of prostatic hypertrophy. The question naturally arises, why should the health of such a large proportion of men begin to be undermined by a harassing, and sometimes alarming, series of symptoms, at a period of life when they ought to be the most comfortable, and capable of their greatest and best work? There must be some cause, very general in its application, and it has been attempted to discover this in the analogy between these pathologic conditions of the prostate and fibroid degenerations of the uterus. I think a sufficient objection to this proposition is found in the very fact that while so many men begin to suffer from the affection in question when on the "down hill" side of life, the great majority of females, on the contrary, after forty-five years of age, enjoy a condition of comfort, and go on to an equable, satisfactory old age. Moreover, the function of the two organs is entirely dissimilar, and, as might be expected, the pathologic conditions, with the exception of the cases in which fibroid tumors have developed, are also entirely dissimilar.

In the great majority of cases of hypertrophied prostate the disease begins and remains in the glandular tissue, the other structures becoming secondarily involved. This view explains the absorption of the prostate which occurs in some cases after its function has been abrogated by the operation of castration. From these considerations, and from careful observation extending over several years, I am warranted in the statement that the first steps in enlargement of the prostate take place in youth. Admitting that general systemic conditions such as gout, rheumatism, and general atherosis may account for some cases, I claim that the chronic irritation and hyperemia, due to excessive function of the gland, often commencing in early life, and maintained during the vigorous period of existence, is sufficient to account for the largest proportion of those who suffer from this malady. It is interesting to find what a history may be developed by careful cross-questioning, even when it would be least expected, of some excessive or unphysiologic use of the prostate, which, starting in youth from ignorance, extends all the way through life to the time when symptoms, more or less severe, call attention to the existence of a urinary affection, and compel such a one to seek the aid of a physician. The subject is so immense and so complicated that in the limited time allotted me it can only be lightly touched, leaving to some subsequent occasion its consideration in detail.

Some, and occasionally all of the following elements enter into the etiology of hypertrophied prostate: (1) the habit of masturbation during childhood, caused either by some local irritation or by the teachings of bad companions; (2) possible and probable associations in the developmental years (that is, from twelve to twenty) with lewd women; or, the ignorant and foolish associations of young persons of the opposite sexes in which the male, though wrong is not intended, is kept in a state of constant or frequently recurring sexual excitement; (3) then, according to the moral status of the individual, follows (or accompanies) adultery or fornication, usually under the conditions of alcoholic stimulation and licentiousness; (4) if marriage occurs, these habits being already established, there is invariably excess. Subsequently there is apt to be objection to the birth of children, and then some unnatural or unphysiologic expedient to prevent conception is resorted to, generally on the part of the male, and this is persisted in oftentimes during years, until symptoms arise which call the attention of the subject to his sexual apparatus. At this period the symptoms may be of a minor grade, and, an intermission in the habits taking place, graver

[1] Read at the Ninety-second Annual Meeting of the Medical Society of the State of New York, held at Albany, N. Y., January 25, 26, and 27, 1898.

symptoms are not presented until later in life, although in the meantime the hyperemia, which has existed from youth, has caused the gradual development of the tissues composing the prostate. Even at this point in the individual's life, if the advice of the physician is sought, a greater or lesser degree of prostatic enlargement will be found to be present. Therefore, I believe that I am correct in the observation that a certain degree of hypertrophy of the prostate is present in many men long before it is suspected. Although surgeons have not considered it generally necessary to explore the bladder of young men (say about forty years of age) for residual urine, they have often been surprised to find many men retaining a small but varying proportion of the contents of the bladder. In some of these cases it cannot be said that at this period of life a self-perpetuating enlargement is presented, because, in many, treatment is successful, and it is even possible by proper remedial applications to effect a reduction in the size of the already enlarged gland, but if the presence of residual urine is to be regarded as one of the symptoms of hypertrophy of the prostate, this condition will be found present oftener than is suspected.

Usually the first evidence of the existence of prostatic hypertrophy is a sense of irritation at or about the neck of the bladder and some variation from the normal sexual condition. Such a patient may at times experience a sense of fulness in the perineum, but unless there has been an acute inflammation of the prostatic urethra there is usually no pain incident to the early stages of this affection. As time goes on a slight increase in frequency of urination may be noticed, and also a little tardiness in starting the urine. The stream of urine is not usually changed in volume, although at times it may be somewhat smaller than usual, and this fact should be borne in mind in differentiating this affection from stricture of the urethra. Gradually, with occasional intercurrent exacerbations, the calls to urinate become more frequent, but following micturition there is a sense of relief, and the individual is not aware that he does not completely empty the bladder and that the latter is gradually becoming fuller and fuller. At this time he may complain of a dull pain over the sacrum or in the lumbar region, which is generally treated as "rheumatism" by means of domestic remedies. Still later the bladder becomes distended, the hydrostatic pressure gradually thins its muscular layers, and there is now more or less atony of this viscus, as manifested by a slow, feeble, dribbling stream of urine. There may also be a relaxation of the cut-off muscles surrounding the neck of the bladder and prostatic urethra. This permits a small quantity of urine to enter the urethra, and then there may be a constant and tormenting desire to urinate, with perhaps involuntary evacuations of a few drops, or even a decided "overflow." The latter is apt to take place at night, during the relaxation of sleep, and the individual has the added misfortune and mortification of wetting his bed. At this juncture, if not before, medical advice is usually sought, and the question arises in the mind of the attending physician,—what is the cause of this frequency and perhaps involuntary urination? It will not do to say that such a patient has "incontinence of urine," and prescribe alkalies and diuretics, for these would only make matters worse by increasing the volume of fluid in the already over-distended bladder.

If an adult presents the series of symptoms which have been narrated, and especially if he has the nocturnal involuntary urination, a careful and discriminating diagnosis must be made; for these symptoms point to some obstruction which the bladder has long been endeavoring to overcome. Stricture of the urethra must be excluded by eliciting the patient's history, and by a careful and aseptic exploration of the urethra with the *bougie à boule* and sound. The latter may take the place of a searcher at this point in the examination and furnish evidence of an obstruction at the neck of the bladder, either by failure to enter the viscus, or by the amount of rotation or depression of the handle required before feeling its point free in the bladder. In general, a searcher after the Sir Henry Thompson pattern is the best exploring instrument, and will often enable the physician to outline the prostate with great accuracy. The passage of a catheter into the bladder, and the discovery of a varying amount of urine remaining after the patient has been requested to urinate and expel all that he can spontaneously, will usually make the diagnosis clear, especially if added to the evidence furnished by the searcher. The simple passage of a catheter into a supposedly empty bladder may often suffice to establish the diagnosis, but cannot be relied upon in a doubtful case; for enlarged prostate is not the only cause of residual urine. Digital examination of the prostate by the rectum should supplement the examination, and may reveal a large, full-lobed, or swollen and sensitive prostate gland, but the diagnosis of retention due to hypertrophy of the latter should not be based upon this method alone. Here it should be remarked, that at this period a new series of symptoms is liable to be manifested from the possible advent of urethral fever, or cystitis, or both.

It should be remembered that it is not the presence of residual urine alone that is dangerous, al-

though when large in quantity such may cause a serious condition of vesical atony, with perhaps a secondary dilatation of the ureters and congestion of the kidneys from back pressure. The presence of residual urine always renders the bladder liable to infections. Normal urine does not necessarily cause inflammation of the bladder, but residual urine, and the consequent congestion due to the efforts of the bladder to expel its contents, prepares the way for the development of infection of the bladder. From the foregoing it follows that the first introduction of a catheter into the bladder of a patient presenting these symptoms should be regarded as a surgical operation, and must be conducted with the most scrupulous attention to surgical details. The meatus and penis should be carefully scrubbed with soap and water. Clean towels if obtainable, if not, sterilized gauze, should be so placed as to surround the penis. The hands of the operator should be carefully prepared with soap and water, and finally scrubbed in pure alcohol. Then the penis and the urethra should be irrigated with an antiseptic solution, and for convenience and ready adaptability, a solution of salicylic acid (gr. viii to Oi) may be used. Then the catheter, which has been previously sterilized with formaldehyd gas or formalin solution, should be removed from its wrappings of gauze, smeared quickly with a sterile lubricant, and, maintaining a current through it of the antiseptic solution, should be carefully and gently introduced. The lubricant which I prefer is made for me by Van Horn & Ellison of New York, and is composed of Irish moss, with the addition of eucalyptol (1–1000) and formalin (1–2000). The first introduction of the catheter into a bladder in which there is presumably residual urine is so important and may mean so much to the patient that, in my opinion, he (or some member of his family) should be previously informed that although every precaution will be taken, there is a possibility of infection of the bladder and consequent cystitis.

In regard to catheters, one should be chosen which will be easily admitted by the meatus. It should be a soft rubber instrument with a solid tip, and its introduction should be made with the utmost slowness and gentleness. The urethra is the habitat of micro-organisms, many, but not all, non-pathogenic, and the urethra and bladder will be made more vulnerable and liable to infection in proportion to the damage to the epithelium which is caused by the introduction of the instrument in question. Moreover, if there be any reason to suspect that the individual has any catarrhal condition of the colon or rectum, or if he has been liable to chronic constipation, the first use of the catheter should be postponed, if possible, even for diagnostic purposes, until the bowels have been thoroughly emptied by free catharsis or by a high enema, and perhaps irrigated with a weak solution of chlorinated soda. This is for the purpose of preventing infection of the bladder by the development of the bacillus coli communis.

The foregoing diagnostic suggestions are made with a case in mind in which there is yet spontaneous urination. If, however, the case presented is one in which complete retention has suddenly occurred, the patient, not being able to pass any urine except perhaps in drops, and whose agonizing attempts to evacuate the contents of his bladder are producing an aggravation of all his symptoms, no delay, excepting the reasonable time which should be allotted to the preparation of instruments, can be permitted. Relief must be speedily attained or the condition may become serious. Absolute cleanliness is, of course, essential. Though one form of catheter may not suffice, the first one to be tried is the soft and flexible instrument such as previously described. Its passage may be facilitated by the previous introduction of 20 to 30 minims of a four- to eight-per-cent. solution of eucain after the urethra has been irrigated. Eucain is somewhat slower in its action than cocain, and six or eight minutes should be allowed for its absorption before local anesthesia will be obtained.

If the soft catheter fails—on gentle manipulation—to enter the sensitive and swollen prostatic urethra, then resort may be had to one, either with an angle at the end (*coudé*), or one with two angles (*bi-coudé*), or to one with a curve and also a tapering, bulb-pointed end, known as the "natural-curve catheter," and which has been of the greatest use to me. Even these may fail, and then resort may be had to other forms, or to a carefully sterilized silver instrument with a large long curve—known as the prostatic curve. But if these successive steps cause traumatism of the urethra, as evidenced by a few drops of blood oozing from the meatus, and it is manifest that the manipulations are to be prolonged, I advise, in view of the safety of the patient, that all instrumental attempts by the way of the urethra should be discontinued, and the over-loaded bladder relieved by suprapubic aspiration. Of course, it is needless to say that this procedure should be undertaken with the same careful sterilization of the hands and of the area of puncture, and equal care in the preparation of the aspirating-needle, as in any other surgical operation. Aspiration may be repeated as often as once in four or six hours when carefully conducted, without damage, and with great relief to the patient. A high enema should be given, and in the intervals between the aspirations

hot antiseptic irrigations of the urethra should be instituted, together with hot irrigations of the prostate through the rectum by means of Kemp's tube. These will aid materially in reducing the congestion of the prostate, which added to the chronic state of hypertrophy, has resulted in the sudden attack of retention. In this way a certain amount of spontaneous urination may be restored, but in many cases this will be deferred indefinitely. At this time the conditions are so acute that no attempt should be made to massage the prostate, but subsequently digital massage of the prostate through the rectum will help to relieve the over-loaded blood-vessels of the gland and facilitate the introduction to the "catheter life," which in all probability must now begin.

The question of prolonged drainage of the bladder is, in my opinion, to be considered at this stage only in case the bladder becomes infected, and when the latter cannot be made clean or obtain rest by means of irrigation. This operation can only be considered in relation to a given case, and must be determined upon by the judgment of a competent surgeon.

In order to consider the details of "catheter life" a broad or general grouping of the cases may be made into those in which there is more or less spontaneous urination, and those in which the individual is absolutely dependent upon the catheter. As the latter class is the more important, let us follow the case of a patient to whom we have been called in the emergency of complete retention. Generally, within two or three days, and aided by the measures which have been instituted, the congestion will have subsided sufficiently to enable the introduction of a catheter. Unless great care is exercised in the first few introductions of the instrument minute traumatisms of the prostatic urethra may occur, and the patient suffer so keenly that he dreads the time when the instrument must be passed. This suffering may be modified, of course, by the use each time of the eucain solution, but in the intervals between catheterization something must be done to relieve the sensitiveness. There are several suggestions which may be followed, such, for example, as the continuation of the hot irrigations which were being used during the acute stage, and this same hot antiseptic solution should be allowed to flow through the urethra each time the catheter is used. Massage of the prostate may be instituted with great comfort to the patient, but must not be performed violently or continued too long at each time. Subsequently a weak solution of nitrate of silver, not over 1–5000, to begin with, and gradually increased in strength, may be applied to the whole of the deep urethra, and especially at the bulbomembranous junction, by means of an instrument which will gently distend the urethra at the same time the application is made; or, else by injecting the solution through a catheter of a size which has been found to enter with the least pain; also, the careful and gentle introduction of a sterilized steel sound, smeared with iodoform emulsion, will be found to relieve this extreme sensitiveness. If, in spite of care, gentleness, and patient effort, the hyperesthesia remains, and especially in those cases in which not even a measure of spontaneous urination is restored, or in which infection of the bladder has occurred, and a persistent and painful cystitis persists, some operative procedure must be considered. The first of these, in my opinion, is drainage of the bladder, and though this part of the subject will be presented by my colleague, Dr. Willy Meyer, I may be permitted to say at this time, that whether my opinion in regard to "drainage" being the first operation to consider will be changed by the re-awakened galvanocautery treatment remains to be seen. I shall make some observations in regard to the latter, and trust that my experience combined with that of others, will enable us to ascertain its merits.

To proceed with the consideration of those cases in which "catheter life" is to be led, we will now assume that the irritability of the urethra has subsided and that the catheter can be painlessly introduced. The patient may now be taught to introduce the instrument himself, and also the care of the catheter, etc.; but, first and foremost, the principles upon which depend the maintenance of a sterile bladder and urethra must be forcibly impressed upon him. If at all intelligent, he can understand (since the knowledge in regard to micro-organisms has become so widespread) that he may easily poison *himself*, and that if he does there will follow a long train of complications, the result of an infected bladder. In general it may be said that if the urine remains sterile the catheter may be passed at the patient's convenience, but this should be done once in six hours at least, leaving a longer interval at night, but depending somewhat on how long the individual sleeps.

Many a prostatic patient with sterile urine, and yet dependent upon the catheter for emptying his bladder, will sleep eight or even ten hours without being awakened by a desire to urinate. So long as the urine remains clear and sterile no necessity for washing the bladder exists. Even after the patient has become established in the habit of using the catheter and has acquired the skill and facility which many of these patients do, he should visit his physician at regular stated intervals, in order that the first evidence, even though slight, of infection may be ascertained and, if possible, immediately remedied.

Unfortunately, many of these individuals become so self-confident and so satisfied with their condition that infection occurs insidiously, increases gradually, and suddenly there is an explosion of cystitis, which may or may not be accompanied by an intercurrent prostatitis. I am in the habit of humorously informing such patients that they should periodically submit themselves to the inspection of their medical advisers on the same principle as that with which they cheerfully pay the fire-insurance premiums upon their property.

In case cystitis has supervened, what shall be done? During the acute stage the patient should be put to bed, placed upon a milk or light diet, and an antiseptic administered by the mouth which will be eliminated with the urine. I am now well pleased with the use of benzosol for the purpose. It may be given in 2- or 3-grain doses as often as every two hours, but I have given it in 5-grain doses without resulting harm. It is usually well-borne, does not set free carbolic acid like salol, and in the intestines (chiefly) is transformed into guaiacol and benzoic acid. The use of Kemp's tube is also indicated in this stage. Now resort may be had to irrigation of the bladder, and if the patient is seen early enough the effect of the infection may be aborted by careful washing of the bladder with a stronger solution of nitrate of silver than I have mentioned.

It is surprising sometimes to see how a threatened severe attack may be modified by the introduction into the bladder of a solution of nitrate of silver of even a strength of 1–1000. Here let me say that this must be gently accomplished. The bladder-walls are congested and are contracting more frequently and vigorously than normal, sometimes with a marked degree of tenesmus, and if a large quantity of fluid is injected or allowed to run in with force, the affection will be aggravated. It is best to be content to inject only an ounce or two ounces of the solution, allow it to run out, and then repeat the injection. The first effect is an irritation. The patients experience what some of them jocosely call a "red-pepper" feeling, but they receive so much relief that they often ask for a repetition of the "red pepper." If this does not give the expected relief, then frequent ablution of the bladder—that is to say, three, four, or even more times a day if the urethra will bear the introduction of the catheter, with a mild antiseptic solution, must be resorted to. The first effect of the solution upon the mucous membrane must be studied, and sometimes it may be necessary to employ such a mild irrigating fluid as normal salt solution, which may be made extemporaneously by dissolving one dram of chemically pure chlorid of sodium in a pint of hot, sterile water. As the case becomes more chronic and the bladder less sensitive, irrigations may be less frequently employed and the fluids used may be varied according to the amount of pus and mucus present. Once in three or four days the physician may use the solutions of nitrate of silver as suggested.

In the consideration of those cases in which a certain degree of spontaneous urination remains, the first question which presents is, what rule shall govern the employment of the catheter? This depends largely upon the amount of residual urine, that is to say, the average amount of urine which remains in the bladder after each active urination, and upon the sensibity of the latter organ. In many cases there is no accumulation of urine beyond this average amount which remains at or about two ounces, excepting during some intercurrent affection of the prostate which may cause an increase in the degree of obstruction. If the residual urine is normal in quality, that is to say, is not infected, is normally acid, contains no crystalline elements — in other words, if of a bland, non-irritating character, the bladder does not resent its presence, remains quiescent, and the patient is not conscious of any irritability of the viscus. In such subjects, and under such conditions, it is not necessary to use the catheter at all, but if the urine changes in quality, and especially if there are obscure pains over the sacrum or in the pelvis, then it may become necessary to withdraw even this small amount of urine—particularly at night, in order that refreshing and undisturbed sleep may be obtained. In some individuals, even one ounce or less of residual urine, if the latter, though sterile, be abnormal in other respects, will irritate the bladder, and therefore should be withdrawn.

As has already been remarked, in these cases of sterile urine it is not necessary to resort to washing the bladder; but after the bladder has become infected the question arises how often shall it be irrigated. Only general directions can be given in answer to this question. The repetition of washing will depend largely upon the amount of pus and mucus present in the urine, upon the frequency with which the patient is called upon to urinate, and also upon the general irritability of the nervous system of the individual. Some persons require daily ablution; others, once in two or three days, and others again, not oftener than one irrigation a week. The interval should be that which suffices to keep the patient comfortable—thus, many men continue for years to urinate but once in four or five hours, and are not disturbed at all during the night. After the patient has learned to introduce the catheter the most important instructions which can be given

him are as to the care of this instrument. The form and kind of catheter having been adapted to the individual, directions which will keep it aseptic must be strenuously enforced by the physician, and rigidly followed by the patient. In my experience, these directions in order to be adhered to by the patient under all conditions, must be simple. Even in the case of medical men who are the subjects of prostatic hypertrophy, and who from their calling are supposed to know the value of thorough asepsis, I have found it necessary to make the directions as simple as possible, in order that they might be followed. Heretofore, thorough washing of the catheter with soap and water after each use, and then immediately before its use, steeping the instrument in boiling water and then in the solution which is used for washing the bladder, has proved satisfactory in some respects, but of course not entirely so. Here I may say that the general intelligence of the patient and the resistance of his tissues have much to do with the prevention of infection.

Unquestionably, a simple but efficient and non-destructible method of rendering and maintaining catheters thoroughly aseptic has long been required, as well as a means which can be readily employed by our patients. It seems to me that the question of catheter antisepsis has been solved by the application of formaldehyd. To this purpose many experiments have been made with this gas, but its employment is not, as yet, within the reach of everybody. I employ in my office a Lilly's appa ratus which generates the gas directly from wood alcohol, and catheters and other instruments may be exposed to its influence for hours. Lately my attention has been called to a fallacy in the use of the gas, and I may be allowed to quote from a recent paper by Dr. Park of the Health Board of New York City, who made some observations upon the diffusibility of the gas in long-closed tubes, such as we may consider a catheter to be. For example, he filled a glass tube with colonies of bacteria and noted that those at the extreme end of the tube were not touched by the gas. He drew the inference that although the gas entered each end of the catheter there might be a zone in its center untouched by it. Hence, it appears that a current is necessary for the transmission of the gas through the catheter or to the end opposite to that at which the generation of the gas occurs. Therefore, since the polymer of the gas, known as paraform, which is in the form of powder or tablets, and which volatilizes, has been used for the purpose of maintaining catheters sterile while suspended in glass tubes or in boxes, this source of failure should be remembered.

In order to ascertain whether the solution of formaldehyd called formalin (a forty-per-cent. solution of the gas) would answer the purpose, and to ascertain the strength of the solution necessary to render catheters sterile, I took three catheters which had been used by patients; one which had been used for the purpose of withdrawing sterile urine, and only used three or four times; another which had been used by a patient for some mouths, but whose bladder was infected; and a third which had been in use nearly two years in a moderately infected bladder. These catheters had all been treated in the same way by the persons who used them; that is to say, they had been carefully washed in soap and water immediately after use, then steeped in boiling water, and also steeped in boiling water immediately before being passed into the urethra. In the first instrument referred to staphylococci were found—a non-pathogenic and a large pathogenic bacillus; in the second, a large coccus and a diplococcus, the latter differing morphologically from the gonococcus of Neisser; in the third, staphylococci and streptococci, and a large spore-bearing non-pathogenic bacillus were found. A one-per-cent. solution of formalin was used. This killed all pathogenic germs after fifteen-minutes' immersion, but it should be observed that in sterilizing catheters in the liquid formalin care should be taken to see that the air confined inside is displaced (by the liquid) by a process of stripping or milking. This I regard as highly important, and desire to call especial attention to it.

From the foregoing may be deduced the following general directions, which must be rigidly followed by the patient:

The soft catheter with solid tip is the best to use if possible. If a rigid one is required, one made of elastic webbing, with a curve or bend at the point which will be the most comfortable for the patient, is preferable. A new catheter must be treated with the same care as to cleanliness and asepsis as one which has been in use. If possible it should be exposed to the vapor of formaldehyd; if not, it should be immersed in a solution of formalin (one- to two-per-cent.) during at least fifteen minutes. Then it should be rolled in a strip of bichlorid gauze or placed between the folds of a perfectly clean towel. Each catheter should be kept in a separate receptacle or closed drawer where dust cannot find access to it, and where it cannot be handled except by the person who is to use it. If the patient's necessities require that the instrument must be carried about with him, it should be kept wrapped in several layers of bichlorid gauze, and outside of this should be placed a wrapping of "waxed" (parafin) or parchment paper held firmly by rubber elastic bands. At the time of use the patient must thoroughly clean his

hands and rinse his fingers in pure alcohol, of which he should always have a quantity on hand. In the meantime the catheter should be lying in the formalin solution. Then, after shaking it and wiping off any drops which may remain upon it with a piece of clean gauze (to avoid irritation of the urethra with the solution), and smearing it with the lubricant already referred to, it may be gently introduced. Immediately after use the catheter should be thoroughly washed with soap and water, steeped in the solution of formalin and then carefully put away in gauze or clean towels in readiness for the next use. If the individual is dependent upon his catheter, and in consequence must have one at his place of business, it is well to provide one sterile instrument for home and another for office use—to be cleaned as well as possible immediately after using and then put away for thorough sterilization on return to the base of supplies.

I have a patient who has a rule never to use one catheter more than a week. He buys them by the dozen, is very particular in their care, and at the week's end throws the catheter away and starts in with a new one. He maintains his bladder in an admirable condition, and I may say that I rarely see him, though he comes in for an occasional inspection, and feels well repaid for the care which he exercises.

SOME OF THE DANGERS SURROUNDING THE DAIRY.[1]

By E. F. BRUSH, M.D.,
OF MT. VERNON, N. Y.

If the dairy is suggested to the every-day urban citizen, his imagination immediately conjures up the fair and buxom milkmaid, the foaming pail, the breath of the sweet-smelling kine, luscious cream for his oatmeal and strawberries, golden pats of butter, and bountiful, innocent sweetness, milk and honey. It may be owing to this sentimental idea of the dairy that so many take kindly to raw milk, while having at the same time an abhorrence at even the thought of eating raw meat from the same animal; when, actually, the danger of contagion, disease, and the ingestion of impurities are far greater from the milk than the meat. Few people, I believe, realize the menace which lies in the milk-supply of cities. Milk which is dangerous, and perhaps deadly poisonous, appears just as innocent, innocuous, and deliciously nourishing as the fluid that is so in truth.

In many of the dairies supplying milk for food nearly everything is either totally wrong or not quite right enough to produce a wholesome product. It is well known that the dairy cow is subject to numerous grave diseases, and many of her maladies are, we know, the same as those which afflict the human race, and it is also an established fact that any disease in the cow affects her milk perniciously. Every one who observes current literature on the subject knows that there are several articles of absolutely refuse material which are used as food for the dairy cow, while she is expected to give in return one of the highest types of food for human use. The cow is necessarily a delicate creature. What condition may be imagined, except actual disease, that is more opposed to robustness, vigor, and hardihood to withstand the shock of cruelty, bad food, and dirty surroundings than maternity and lactation? The cow, while giving us milk almost constantly, at the same time sustains a fetus; and so it is only reasonable to affirm that the dairy cow must receive solicitous attention, gentle treatment, and absolute cleanliness in her surroundings and feeding if it is expected that she will supply milk fit for human food. It was long ago discovered that what affects the mother affects the nursling, sometimes even so far as to cause the death of the latter.

Unfortunately, it is the exception to find a dairy in which the cows are treated kindly and fed or housed in a cleanly manner. At the present time health authorities appear to recognize nothing but tuberculosis as the sum total of all the disease and danger contained in the improperly managed dairy. The sources of possible contamination which surround the milk after it is drawn from the cow are many and serious on the majority of dairy-farms as they are conducted at the present time, and it is this part of the hygiene of the dairy to which I particularly wish to call attention now, because this branch of the subject receives everywhere less attention than it deserves, and I believe that when we are able to exclude the diseases which arise from milk-contamination in the dairy, outside the cow, we will be better able to trace some of the epidemics which find origin in the animal herself. Until all the dangers of the dairy are recognized many of the more grave and menacing ills cannot be remedied.

It must be remembered, in considering milk, that there is no other article of food just like it. There is no food, fluid or solid, which presents so many favorable conditions for the absorption of the tangible material of disease and for its preservation and multiplication, and in no other instance is a medium found for the conveyance of infection by which so much harm can be accomplished in such a very short time. Of course, a certain degree of heat will disinfect milk, but even a high temperature will not eliminate the toxins already contained therein.

[1] Read at the Ninety-second Annual Meeting of the Medical Society of the State of New York, held at Albany, N. Y., January 25, 26, and 27, 1898.

We are constantly searching for a specific remedy for scarlet fever and other often fatal diseases of childhood, while frequently permitting the bacterial cause of these diseases to be fed to our children in their milk. Many of the diseases of infancy may be rendered much less frequent or even altogether eradicated by proper attention to the hygiene of the dairy, and I believe that the achievement of success in this line is being delayed by the futile efforts of well-meaning physicians, who imagine that they are correcting the evils of a bad milk-supply by modifying, Pasteurizing, sterilizing, adding animal and chemical compounds, and by otherwise changing the character of the milk.

Around every dairy is a multitude of dangers—dangers, unfortunately, which are not always appreciated or avoided, and hence culminate in disaster. There are many other animals about the dairy besides the cow which menace the dairy product, often as seriously as a diseased cow herself. Horses, dogs, cats, rats, mice, and fowls undoubtedly are often the direct means of infecting milk, and of thus passing contagion along to the human race.

Cats loll and purr around many dairies all day, and it is a very common thing to see a wheezy old cat lapping warm milk from a pail or other milk container. These animals are known to succumb to a throat trouble which appears identical with human diphtheria, and it is also known that they die from many tuberculous forms of disease. So it is not unreasonable to ascribe contagion to these animals when they are allowed the freedom of the diary. Dogs prowl about the farm day and night, and very often depend upon the carcasses of dead animals for their living. Cows, horses, and pigs often die of septic and contagious diseases; the carcasses are hauled into the woods or fields, away from the house, and there left exposed as meat for the farmer's dogs. These dogs come back and lap the milk from the pail, lick the empty milk vessels which are never properly cleaned; and can there be doubt that the milk is thus infected? Where this danger exists in a dairy it is practically unlimited. Rats and mice infest the ordinary dairy; they get into the milk and the milk-vessels. These animals also have their diseases, and, therefore, the element of danger and disease from these pests must be acknowledged. The poultry around the farm are sometimes very numerous, and not always healthy. The diseases to which they are subject are many, and, owing to their high, normal body temperature (108° F.) there is no other animal which so readily becomes tuberculous or which dies so quickly from this disease. On some dairy farms the hens are everywhere, in the cow stable, in the milk-house, in the dwelling-house, and even in the milk-pails. The dairyman, as a rule, has a family of children who are often attacked with the grave diseases of childhood. The milking vessels are frequently washed in the house, and not unusually there is a close connection between the house and the dairy, and sometimes the living-house is, itself, used as a dairy-house. It requires no argument to point out the dangers here; in fact, numerous epidemics have been traced to such a source.

Those who milk the cows are not always free from disease; often we see the milker with hands that are cracked or sore. One of the dirtiest habits which exist in many dairies is that of wetting a cow's teats to lubricate them, to make the milking process easier to the milker. This custom, not rare, unfortunately, is the most common nasty habit permitted in many dairies. If it were not for the good that is sure to follow the agitation of these matters I should hesitate to record that I have myself seen milkers spit upon their hands to wet the teats before they began milking, and then, when there was a certain quantity of milk in the pail, dip their dirty hands into it, and keep the teats dripping wet during the whole process of milking. Cow's teats should not be wetted in any manner, especially in winter, even to wash off dirt if it is already there. This should be removed with a brush or a dry towel. Wetting of the teats very often leads to chapping, and chapping to cracks, and these cracks often become running sores from the constant irritation of the milking process.

In these days of bottled milk the danger of spreading contagion is vastly increased. Bottles which go into rooms where children are suffering from any of the contagious diseases must be a source of danger if they are not subsequently sterilized. Quite recently I had occasion to visit a man who did a large bottled-milk business in New York City. The milk came in wagons from the upper part of Westchester County, and he had a horse-stable half way between his source of supply and New York. Here his horses were changed. All the milk came to this stable in cans, and the empty bottles came back here from New York to be washed. He had two wooden troughs in this stable, and a stove with a large kettle to heat water, and the bottles were washed here in lukewarm water with sal soda, rinsed with cold water, and then filled from the cans.

I think, if some of us followed these bottles around and had seen where some had been, we would want them pretty well steamed and sterilized before we drank milk from them. It is often a source of wonderment to me why we do not have more direct and palpable evidence of trouble arising from just this state of affairs. Of course, there are unfortunate results from this sort of carelessness; but

how much or how little we are not always able to say. We ought to be able to prevent it by insisting that all milk containers be sterilized with steam under pressure after each usage.

When the dangerous elements are recognized and eliminated from the dairy, then it only requires that the cows be healthy, properly fed and cared for, in order that we may have milk fit to drink and to feed to the baby, without the intervention of the chemist or any of the prevailing laboratory methods, which at the best are only questionable makeshifts.

A GROUP OF AGED PATIENTS.

By J. H. EMERSON, M.D.,
of New York.

One morning last winter I had occasion to call upon four patients whose united ages amounted to 346 years, and in thinking over others, whom I had recently seen, I realized that there were enough who were over eighty years of age to form a rather interesting group. I have, therefore, written down such facts as constitute sketches, rather than detailed or complete histories, of a few of them, in an effort to trace such features referable to advanced age as they present in common, and to give some account of their management. I hope in this way to furnish a topic for discussion, and, it may be, reach some generalizations of clinical utility as to phases of disease, and some of the demands of treatment, in the aged.

Case I.—Female, aged ninety years. The patient lived the ordinary life of a well-to-do woman in society, spending the winter in New York and the summer at Newport until the autumn of 1884, when she returned to town on the last day of October, exhausted, feeble, and breathless, so that she was barely able to mount the single flight of stairs to her bedroom. I found a feeble and dilated heart, albuminous and phosphatic urine, and subsequently casts. The patient was short in stature, and at this time very stout. Under the influence of rest in bed, with the administration of mercurials and digitalis, attention to the bowels and diet, and good nursing, she gradually recovered from the most urgent and distressing symptoms, and attained a great measure of comfort. During this period she lost, it is true, the greater part of her flesh, and also her muscular strength, so that although in the following summer she went out of town to a place but a few miles off, it was necessary to bring her back the whole distance in a carriage, and since then she has remained on one floor of her house, occupying a north room during the hot weather, and a south room the rest of the year, but for many years now never leaving her bed except when lifted out to have it made.

The physical ailments which I had to encounter in this case were, in addition to the feeble heart and degenerated kidneys, an umbilical hernia, which would occasionally escape in spite of a bandage constantly worn, a lateral as well as angular curvature of the spine in the dorsal region, an obstinate constipation of the bowels, and of late years a pyelitis, with probably the development of a sac in relation either with the pelvis of the kidney or with the ureter. Thus, the urine will sometimes remain clear and free for months; then will come a period of pain, nausea, vomiting, and perhaps some febrile movement with very scanty elimination, and sometimes the presence of a large mass in the left side of the abdomen.

Relief comes only with free urination, sometimes about one-third part of the excretion for days together consisting of tenacious, phosphatic, purulent matter. These complications, especially those arising from bowels and kidneys, very often lead to acute disturbances of the stomach, with sometimes an irritating salivation, but more frequently nausea, constant gaseous eructations, vomiting, and syncope, so that when these attacks are threatening the nurse keeps mustard and ammonia ready for instant use, hot water at hand, and the hypodermic syringe ready charged with brandy or tincture of digitalis. The prompt use of these measures has again and again rescued the patient from profound syncope before the nearest physician could reach her. Then she enjoys long periods of placid comfort, lying from morning till night propped up on her left elbow with many a little cushion, holding her paper or book, reading everything that is new and entertaining, and keeping up the most lively interest in all the affairs of the city and the great world. The left pectoralis major muscle, meantime, has acquired a surprising strength and firmness in her otherwise emaciated frame.

Of course the treatment has long contemplated nothing but such regulation of the bowels as will keep the stomach available for sufficient supplies of food and the meeting of emergencies as they arise; for the heart is quite equal to the minimum demands which are made upon it by one who rests absolutely in bed all the time, whose passions are all in abeyance, and whose stomach is never overloaded with food. The question of feeding has often been quite puzzling, but the solution of it has always been aided by finding how very small the actual demands of her system are. The proportion of alcohol has been gradually increased. Many changes have been made from time to time, but for months past the following has been the almost unvaried dietary: During twenty-four hours she takes two cups of black tea, being about half milk, one piece of zwieback, one lady finger, one soft-boiled egg, two cups of bouillon, and sometimes the soft part of a baked apple. She also disposes of one gallon of brandy in six weeks and one bottle of sherry a week, making about three ounces of the former, and three and one-half ounces of the latter *per diem*.

Case II.—Female, who died about January 1, 1897, in her ninety-first year, and whose case I have already mentioned before this society. Her death was directly due to the development of malignant disease

of the stomach, and, probably, of the large intestine, which had followed upon the cancerous degeneration of what Dr. Abbe referred to as an explosion cyst, originally a cystic tumor, over the left scapula, and which had remained an unhealed ulcer during four or five years. When she came under my charge, about three and a half years ago, I learned that she had been using during many years suppositories of opium and extract of belladonna, the dose not having been increased, however, since it was originally prescribed, nor did she increase it till about two years ago, when she doubled it, and after that took daily a dose of 2¼ grains of opium, and ¼ grain of extract of belladonna. She had also, many years ago, been treated with nitrate of silver to an extent which had left a permanent stain upon her lips and cheeks. Her arteries were rigid, she had both mitral and aortic heart murmurs, and the urine showed a slight but constant quantity of albumin.

Having always been in the habit of indulging her taste for rich food she suffered much from indigestion and lack of appetite, troubles which were naturally increased by the constipation due to her opium habit. She would often pass a number of days without an evacuation of the bowels, and then relieve herself by a process of excavation aided by enemata. These methods had resulted in an atonic state of the large intestine, so that no ordinary dose of cathartics produced anything but discomfort. Finally, I succeeded in producing evacuation of the bowels by means of capsules of blue mass, extract of colocynth, and ipecac., to which, at Dr. A. A. Smith's suggestion, I added extract of cascara.

About the end of last October, however, epigastric pain and tenderness, with occasional vomiting, which shortly showed a coffee-ground character, and the detection of a small mass in the epigastrium to the right of the median line warranted the diagnosis of malignant disease of the stomach. From this time treatment had to be limited to the administration of such concentrated food as she could be persuaded to swallow, including liberal quantities of brandy. She was also given cathartics and narcotics. The adjustment of the latter proved to be a most difficult problem, both on account of her long addiction to opium and of the profound depression produced by doses sufficient to cause sleep. She could not sleep without opiates, and the pain also demanded their use, yet she absolutely refused to go to bed. She would at the utmost spend but a few hours lying on the sofa, but most of the entire day and night sitting up in her chair and resisting in every way she could all efforts to make her sleep, to the despair of her nurses. I had actually twice to hold and etherize her, which secured several hours' sleep.

If a sufficient dose of morphin was given to procure a few hours' sleep, the succeeding period was marked by hopeless depression of spirits, with constant restlessness and fear of impending death. Coffee, lavender, bromids, codein, Squibb's liquor opii compositus, and chlorodyn, proved useless either to stimulate her, or to prolong in moderate degree the narcotic effect of the morphin. So that ultimately, for some weeks, she received at about 9 P.M. one of the suppositories, followed, about midnight, by a hypodermic injection of ¼-grain of morphin, and about 3 or 4 A.M. either a second suppository or ⅛-grain more morphin, with, for a while, trional instead of a second dose of morphin. Such medication had to be suspended now and then to allow of the administration of cathartics, although toward the end there was a diarrhea, which was regarded as evidence that some portion of the intestinal canal below the stomach had become involved in the disease.

Case III.—Male, aged eighty-two years, has a feeble heart, slightly enlarged, but no valvular lesions. His urine contains a small smount of albumin, but casts have not been found. The earliest symptoms of failing health began to be noticeable some nine years ago, and were, a gradually increasing slowness of gait, leading to shortness of breath and a tendency to puff, or a prolonged expiration, accompanied by a whistling noise. He frequently had to stop and lean against a railing until he gained breath or force enough to go on. A very slight acclivity materially increased the trouble, and one reason why he can walk more comfortably at his home in the country is because the town in which it is situated is almost absolutely level. By degrees, however, this dyspnea became noticeable even when he was sitting in his own library, more particularly if he tried to talk, of if his visitors were many, or if they bored him. Close attention was paid to his diet, for he had been accustomed to hearty and rather rich food. Regular action of the bowels was readily secured, and from time to time I gave small doses of calomel.

The lungs have presented symptoms of emphysema, but of the senile or so-called atrophic type, without asthma, or more than occasional and moderate bronchial catarrh, though there are often fine râles on inspiration in the lower lobes of the lungs posteriorly. He has never suffered from orthopnea, always finding comfort in the recumbent posture. The most serious intercurrent attack he has had occurred two years ago, when he suffered for some weeks with atony of the large intestine, accompanied by some pain and irregular action of the bowels, and leading to great debility. As a result of this he gave up his house where his library and dining-room were two stories away from his bedroom, and took a large apartment fronting on Central Park, where he has an abundance of air and light, and all rooms on one floor. Here, under the care of a competent woman attendant, he lives with all the comforts his physical disabilities will allow.

So far I have said little of his medical treatment. I have found it impracticable to give him iodids, and although Dr. Loomis, who saw him in consultation, urged them, a further trial proved them to be so disagreeable to him that I gave them up.

Various other preparations, burning of niter paper, etc., have but moderate effect in relieving the dyspnea, and the best results have been obtained from a pretty steady administration of small doses of digitalis, strophanthus, and belladonna, in varying pro-

portions. One of the most interesting features of this case has been the gradual change in disposition. From having been as a practising lawyer a man of positive convictions, ready to say a sharp thing even at the expense of another's feelings, showing often his rough side to those about him, and liking to do his own work in his own way he has gradually grown more genial and gracious in speech and manner, craves sympathy, is absolutely submissive to medical authority or the suggestions of his nurse, and seems to find nothing more distasteful than making up his mind to do a new thing or to exert himself physically or mentally. Often he will smile, but shake his head at the proposition that he should go even into the next room. Meanwhile he gives freely to charity, and takes pleasure in seeing his friends who call upon him.

Case IV.—Female, aged eighty-nine years, presents another instance of varied pathological conditions and much suffering, which still have not prevented the attainment of great age. She has suffered over twenty years from convulsive tic, for five years from chronic inflammation of the subcutaneous connective tissue of the legs below the knee, with occasional eczema and obstinate ulcers, making her a prisoner in her room, and three years ago she had an attack of pneumonia which was interesting in three particulars, *viz.*: she recovered from it; the confinement to bed cured the ulcers on her leg, and third, she learned the use of whisky, from which she has since been unwilling to part. It may be thought, naturally enough, that this is not a record particularly creditable to the physician in charge, but I had called in, for surgical consultation, two members of the Clinical Society; had exhausted my own resources on the *ulcera cruris*, and yet they healed only during the confinement to bed made necessary by the pneumonia, to reappear when she was again able to be upon her feet.

In spite of the demonstration afforded by this experience, no persuasion or exercise of professional authority have sufficed to make her consent to another period of repose in bed. The case furnishes an unhappy instance of a narrow and undisciplined mind, a prey to many an old-time superstition and prejudice, of personal vanity which has grown ridiculous and pitiful with advancing years, and of the evil resulting from the want of personal cleanliness, when the dim eye of age will not recognize its deficiencies, and the attentions of hired attendants and of affectionate relatives are alike wanting or rejected.

As further illustrations of conditions which call for our attention among octogenarians, let me mention very briefly the following cases:

Case V.—Female, aged eighty-three years, now drawing to the end of a life of many trials, which culminated for her personally five years ago in an apoplexy and right hemiplegia. The conditions which persisted were an emotional state with frequent tears, and that form of aphasia in which simple phrases come easily but in which the special word to tell the incident which made an impression upon the mind will not come, on which follow disappointment and hopeless attempts until the faint hold on the idea is entirely lost. There were also some contraction of the forearm and a dragging foot. A placid temperament, a good digestion, sound heart and kidneys, supplemented by good nursing, have prolonged the scene until now increasing drowsiness and debility point to an early fatal termination.

Case VI.—Male, aged eighty-two years. This patient last fall presented a large ischiorectal abscess, the third development of the kind within twenty years, but it healed so promptly following simple incision and drainage that no more radical treatment seemed warranted. He has long had a bronchial catarrh, with some dilatation of the tubes, and twice has had acute exacerbations which required confinement to bed. From early life he has had an irritable bladder, which has made him somewhat of a recluse, and prevented him from doing many things that would otherwise have been attractive. But he does not seek treatment for it, having apparently made up his mind that it is a thing to be endured rather than cured. In spite of his age he still occasionally visits the Produce Exchange, of which he was until recently an active member.

Case VII.—Female, over ninety years of age, has been under my observation but a short time. About eighteen months ago she fell and injured the right thigh, so that she now has to walk with a cane, but fortunately escaped a fracture. About six weeks ago she had what must have been an embolism of some artery of the brain, for she suddenly found herself unable to rise from her chair on account of weakness of the left leg. This was only temporary, although the left arm was of but little use for several days. These symptoms had passed off when I saw her, but I found the most rigid arteries I ever felt. The heart sounds gave evidence of both mitral and aortic disease, while the urine contained a small amount of albumin, but no other evidence of renal degeneration. Both eyes are cataractous, so that she can with difficulty recognize a person who enters the room. Her mind is still alert and intelligent, and it is surprising to see how briskly she can walk in the street, supported on her son's arm, or go about her own apartment unaided. The simplest directions as to diet and the regulation of the bowels, together with the administration of small doses of nitroglycerin, have contributed materially to her comfort.

Case VIII.—A Quaker maiden, ninety-one years of age, two years ago came comfortably through an attack of erysipelas involving the head and most of the trunk. It began at the left nipple in an excoriated area, connecting with a small sinus from which a scanty purulent discharge constantly flowed. The excoriation healed under applications of oxid-of-zinc ointment, and the discharge ceased. Since then it has been useful to her to take about an ounce of whisky daily in divided doses. Another indulgence, from which she will not be parted, even while ill, is candy, of which she secures a supply for daily use. She dozes away much of her day but is bright and sociable at meal times. A year ago

she went to the photographers to have her likeness taken, and spent last summer at Nantucket.

CASE IX.—Female. I desire to mention this case because of the long endurance of malignant disease, the patient dying about a year ago at the age of eighty-one years, after having suffered twenty-four years from an epithelioma, which she first showed me during 1872. It began in the skin of the forehead, a little to the right of the median line, extended down to the root of the nose, to the right eyelid, and ultimately to the orbit. Dr. Prudden found it a typical epithelioma in 1883. At that time I did a plastic operation upon it. I subsequently used various caustic applications, curettings, etc. Dr. Sands operated upon her once, and Dr. Weir twice. After the last operation, which was four or five years before her death, it was surprising to see the comfort she derived and the degree to which the ulcerated surface diminished under the persistent use of a bichlorid lotion, followed by free powdering with iodoform. This patient also had a large fatty tumor in the right axilla.

In reviewing the points of interest presented by these cases, I think there are several which are noticeable and characteristic of the one feature they have in common,—I mean the advanced age of the patients. Thus, all of them are the subjects of more than one marked pathological condition. Persons who reach eighty, much more those who reach ninety years, must be endowed with more than ordinary capacity for enduring the minor ills of life, and the same vitality doubtless stands them in good stead when more serious diseases develop; so that on examining such patients it need not surprise us to find a tolerance of disease in important organs to which the more vulnerable would long before have succumbed. As akin to this, and largely accountable for it, I would place that absence or blunting of acute sensibility, which is a trait of the aged. In earlier life, the functions of all the organs are vigorously and actively performed, the impressions upon all the senses are sharply felt, and meet with a quick response in either mental or muscular activity, giving the keen zest to healthy existence. But the man who has lived through three score years and ten begins to realize that his affairs will go on pretty well even if he does not hurry and drive to accomplish them. So many little stimuli have affected him that a degree of tolerance has been established. There comes a time when even Ulysses or Gladstone no longer cares,

"To drink delight of battle with his peers."

He is satisfied with a placid and uneventful course of life, and finds his recompense in diminished anxiety, less wear and tear, fewer demands on failing powers. He gets a glimpse of the twilight of the gods. If the restlessness of earlier years is maintained, if the old man insists on keeping up the activities and sharing the responsibilities and even the pleasures of middle life, it soon appears that he is not availing himself of the prerogatives to which his years entitle him, and fretfulness and impatience add largely to the physician's difficulties in treating the patient. The gentle amelioration of the temperament and the restful calm that comes from it, are well illustrated in Cases I. and III., and the opposite in Cases II. and IV.

When finally we come to consider what lessons of treatment may be learned from the observation of these aged patients I would first emphasize the value of repose, a striking instance of which is furnished by Case I., in which an overtaxed heart, even in the presence of many and serious complications, has been able to perform its functions with comfort for many years. Next, and as a most important agent in securing the restful life, comes a good nurse, able to take up and bear the many personal cares our patient has long been feeling as a burden. And among the first duties of the nurse, the faithful performance of which may be more manifest, perhaps, to friends and physician than to the patient, will be keeping him or her clean. I have known wondrous changes, appreciable by more than one sense, wrought by such simple care given to those whose own senses were dulled by advanced age. Then, too, the physician must be willing to hold his hand. It is seldom that what is called active treatment is required. He must be satisfied to let many matters take their course, must be content to alleviate rather than cure, to advise against a resort to surgical measures which might be clearly indicated in similar conditions in younger persons.

The nutritive demands of these patients are apt to be small, and it must be recognized that alcoholics in some shape are almost always needed. The small amount of food, the fact that much of it is taken in a concentrated form, the want of active exercise, all contribute to sluggish action of the bowels, and the simpler laxatives are matters of almost daily necessity.

An Extraordinary Case of Extra-Genital Chancre.—At a meeting of the Ophthalmologic Section of the College of Physicians of Philadelphia, held January 18, 1898, Dr. G. E. de Schweinitz described and exhibited a water-color sketch of a case of chancre of the conjunctiva in a physician who became infected during the delivery of a pregnant woman. The physician's face was spattered by some of the discharge, and was hastily wiped off with her apron by an officious bystander. The diagnosis was not made till the lymphatic glands of the face and neck became swollen and the specific eruption appeared on chest and limbs. Under antisyphilitic treatment the ulcer which had appeared on the conjunctiva rapidly healed and all symptoms disappeared.

CLINICAL MEMORANDUM.

A PERSONAL EXPERIENCE IN RENAL SURGERY.

BY ROBERT F. WEIR, M.D.,
OF NEW YORK;
PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, AND SURGEON TO THE NEW YORK HOSPITAL;
WITH THE COLLABORATION OF
EDWARD M. FOOTE, M.D.,
OF NEW YORK;
SURGEON TO THE RANDALL'S ISLAND HOSPITALS.

(Concluded from page 177.)

CYSTS.

WHILE renal cysts, sometimes containing large amounts of fluid and generally single, are found, and presumably are acquired, yet it is believed that the multiple cysts or the veritable general cystic degenerations of the kidney are of congenital origin or begin in early life, and that both kidneys are usually simultaneously involved, though not always to the same extent. Occasionally this transformation with its innumerable cysts is encountered in but a single kidney, but this is so rare that surgical action should not be based on this fact alone. The ordinary cysts—that is to say, those which are few in number and comparatively small, and in which decided renal tissue may be seen to intervene between them—do not call for surgical interference, though they occasionally attain such size as to necessitate operative relief. The hemorrhagic tendencies, with the increased tension which often supervenes and produces renal pain, are usually not to be diagnosed until a surgical puncture or an incision has been made—sometimes not until after a nephrectomy has been performed, as in Case III.

Concerning the true multiple cystic degeneration, an example is given in Case XXXV., in which a surgical error was made. From a too imperfect examination of the other kidney, its rounded inferior end having only been palpated, the deduction of one sound kidney was made and the nephrectomy accomplished. It proved afterward that the remaining kidney, though effective in a previous easy condition of life for carrying on the necessary urinary secretion, yet, with the additional load of elimination, it failed almost entirely, and the patient, though recovering from the operation, died uremic not long thereafter.

While in this instance no difficulty in diagnosis arose as soon as the kidney was exposed, yet I have since seen in consultation with a colleague an example in which, after the kidney had been exposed by a lumbar incision, great difficulty was experienced in determining whether the irregular knobbed masses yielding bloody fluid on puncture were due to multiple cysts or to a neoplasm. Under the impression that the latter existed, nephrectomy was resorted to with a fatal result. The accepted rule of surgery in these cases is that extirpation is not justifiable.

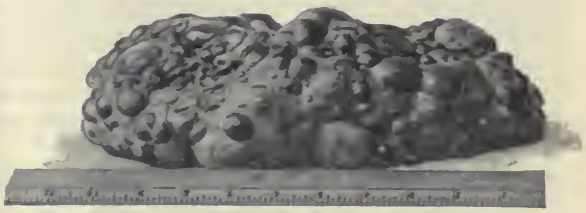
CASE XXXV. *Multilocular Cyst of the Kidney—Nephrectomy—Recovery.*—Caroline B., aged thirty-four years, entered New York Hospital January 7, 1890, with a history of constant and increasing pain during the four previous months, associated with the discovery of a round, smooth swelling in the left loin. Examination showed the left side of the abdomen to be occupied by a solid nodular mass of variable consistency, which reached nearly to the pelvis, and was quite immovable. On consultation, it was supposed to be an enlarged spleen or a retroperitoneal growth. The urine was pale, acid, of a specific gravity of 1010, and contained a trace of albumin. There were no casts, but an abundance of renal cells.

January 10, 1890, a vertical incision was made at the outer edge of the rectus muscle. Upon opening the abdomen the tumor projected itself through the wound and was recognized as a multicystic kidney. It was so badly diseased that it was removed, especially as palpation showed the right kidney to be comparatively free from disease. Gauze was used for drainage.

Although the patient had received only ¼ grain of morphia (by hypodermic injection before the operation), her respirations fell to 4 per minute afterward, and her condition was critical for a time. She also vomited a good deal for several days, but finally recovered, and left the hospital in five weeks after the operation, the wound being not quite healed at the time.

The extirpated kidney was made up of a mass of cysts. It weighed 1038 grams and measured 25x12x10 cm. The vessels and ureter were normal. The individual cysts varied in size from a minute speck to 5 cm. in diameter. Their contents were clear, grayish, and even opaque and black (Fig. 3). The patient, it was afterward learned,

FIG. 3.



Multiple cystoma of the kidney.

made but indifferent progress after leaving the hospital, and some three months later developed edema and died from uremic convulsions. The autopsy showed that the right kidney was moderately enlarged, but that it had also undergone marked cystic degeneration.

CASE XXXVI. *Supposed Appendicitis—Cyst of the Kidney—Multiple Abscesses—Transperitoneal Nephrectomy—Death.*—Alice H., aged thirty-three years, concluded a pregnancy by a normal labor two months before entrance to the hospital. No symptoms were noticed until two days before operation, when there was a pain in the right side, increasing in severity, and followed by a chill and vomiting. Slight vesical tenesmus was noticed.

There was an ill-defined mass reaching from just below the ribs, downward, beyond the anterior superior spine of the ilium, and toward the median line. It was most tender at its lower margin, and dull on percussion, and did not present a clear outline. The abdominal walls were very thick. The patient had a temperature of 102.6° F., and a pulse of 116. The urine was acid, of a specific gravity of 1020, and contained ten per cent. of albumin by volume, and a moderate amount of pus. The diagnosis was doubtful. It lay between appendicitis, with a high-lying abscess, or a ruptured gall-bladder, or renal suppuration.

December 19, 1895, a vertical incision was made over the lower part of the tumor—to meet the probability of its being an appendical abscess. The appendix was found to be normal. The tumor was then ascertained to originate in the kidney, and the abdominal incision was there-

fore enlarged upward and the peritoneum over the kidney incised, peeled back, and sewed to the divided peritoneum of the wound. Aspiration revealed a large cyst containing urine; and as the kidney was evidently further diseased, the ureter was tied with one strong silk ligature and the vessels with another, and the kidney removed. During the manipulation the ligature on the vessels slipped, and considerable blood was lost before it was replaced. A lumbar incision was made for drainage, and the posterior peritoneum stitched together over the bed of the kidney, and the abdominal wound closed. Despite stimulation, hot enemata, and an intravenous injection of saline solution (14 ounces), the patient died within twelve hours.

The extirpated kidney contained numerous small abscesses, especially in its lower two-thirds (of acute origin), and above this there was a large thin-walled interstitial cyst lined with a dense membrane. The renal tissue was the seat of parenchymatous and interstitial inflammation. No autopsy was permitted.[1]

NEW GROWTHS.

The outlook for a patient with a malignant growth of the kidney is grave indeed. As far as is known Kocher was the first surgeon who was able to save such a patient by removal of the diseased organ. That was over twenty years ago. Since then some hundreds of attempts have been made in the same direction, but usually without encouraging results. Up to 1890 a large proportion of the patients operated upon (fifty-two to sixty-six per cent., according to different authors) died from the effects of the operation itself. Since then the results have been better, and according to Wagner the mortality from operation is now not more than twenty to twenty-five per cent. in the hands of the most expert surgeons. Individuals have recorded still better results; for instance, Israel had a mortality from operation of only 12.5 per cent. in twenty-four cases. In the malignant growths in children, which are principally sarcoma, Walker[2] reported a mortality from the operation of thirty-seven per cent. None of these results take into account the deaths from recurrence, but granting that almost all of the patients operated upon succumb either to the operation or to the disease, an operation, in adults, is still advisable, and is indicated in those cases in which the patient's condition is favorable; for thereby a period of comparative comfort of from two to four or even more years is gained, as well as the possibility of a radical cure. In children, however, out of 60 nephrectomies only 4 patients survived a period of 3 years, a result that almost prohibits operation. When one turns to the published histories of these cases to ascertain which were *absolutely unfitted for operation*, it appears that the decision must rest, aside from the patient's general condition, not on the size of the tumor, nor on its duration, but on the amount of existing adhesions. A neoplastic kidney with adhesions is hard to remove, and its dissection is often long and dangerous; so that these patients frequently die from shock and loss of blood. If the operation is successful the patient is also certain to die, either from a continuation of the growth in the vicinity, or from metastatic deposits formed before the removal of the primary focus of the disease.

An early diagnosis is here, as in all malignant growths, most important, and in the case of the kidney it is especially difficult to make. The presence of a tumor may be the first sign observed. Thus, in a case reported by Rovsing,[1] a woman, aged forty-five years, had noticed a swelling in the side, where she had had some pain during four months. The urine was absolutely normal, and the tumor movable. Under these circumstances an easy operation was expected, but the adhesions about the upper part of the kidney were so firm that it was torn in two in the attempt to remove it, and the patient died from shock and loss of blood within six hours.

If the growth originates in the lower part of the kidney, both diagnosis and operation are rendered easier.[2] Unfortunately this is not apt to be the case, for the majority of tumors begin either in the suprarenal capsule and grow into the kidney, or else in the upper part of the kidney itself. Even when a tumor is palpable a diagnosis is by no means certain. One of the most difficult of diagnoses lies between a malignant growth and multilocular cystoma. Even when the latter is bilateral, as it usually is, it may still be palpable only on one side. Here an exploratory incision is the readiest method of deciding the question. When a cystoma or an adherent carcinoma is found, the wound should be at once closed. In some cases a quantitative estimation of the amount of urea excreted in the twenty-four hours may be significant. If cystic or neoplastic degeneration has reached any marked degree, the urea elimination will be so decreased that it will be useless to think of any radical operation.

Other cases of malignant tumors are associated with hematuria. This symptom, again, may be very deceptive; for instead of the painless, constant hemorrhage which we might expect, the blood often comes intermittently, with colic, and with the association of urates and uric-acid crystals or even small bits of gravel, so that the diagnosis of nephrolithiasis is often erroneously made. The loss of weight, the presence in the urine of abnormal varieties of cells, or bits of tumor tissue, frequently will suffice to clear up a case; but these distinctive signs are often wanting in the early stages, and an exploratory operation may be required to establish an absolute diagnosis. Therefore, in every unexplained hematuria, one ought to think of the possibility of a malignant tumor of the kidney.

CASE XXXVII.—*Adenocarcinoma of the Kidney—Abdominal Nephrectomy — Death.* — Charles H., aged thirty-three years, a burly butcher, was suddenly seized with cutting pain in the left lumbar region, and passed a quantity of bloody urine. Similar attacks occurred at not very long intervals, and he frequently passed gravel. In the second year from the first attack the symptoms became much aggravated, pain in the loin was almost constant, and the patient became worn out from loss of blood and suffering. A tumor was noticed in the left flank extending from a point three inches external to the umbilicus, upward and backward under the ribs. It was slightly movable bimanually, and seemed to be about

[1] I now believe that the forward extension of König's incision would have sufficed in this case.
[2] Walker, *Annals of Surgery*, November, 1897.

[1] *Arch. f. klin. Chir.*, xlix, p. 412.
[2] Israel, *Ber. klin. Wochenschr.*, vol. 26, p. 125.

seven inches thick. The urine contained no abnormal elements except blood.

December 2, 1886, an exploratory incision was made in the left loin and the kidney exposed. No calculus could be felt either by thorough palpation or by thrusting a hatpin into the kidney at several points. The diagnosis of sarcoma was made, and it was evident that the kidney was too much enlarged to be removed by a lumbar incision. It was, therefore, decided to resort later to abdominal section for its extirpation. Estimation of the urea showed a diminished excretion, the daily amounts ranging from 219 to 240 grains. This decreased excretion is said by Thiriar to be characteristic of malignant tumors.

January 20, 1887, an incision five inches long was made along the outer margin of the left rectus, the abdomen opened, the intestines pushed aside, and the peritoneum covering the kidney to the outer side of the descending colon incised. The diseased kidney was readily dissected free with the fingers, and its pedicle was tied *en masse* with floss silk. A heavy clamp was placed on the vessels between the ligature and the kidney, and the latter was removed. By the slipping of the clamp a vein which was not included in the ligature bled freely, but it was easily seized and tied (an advantage of the abdominal method of nephrectomy). Considerable bleeding took place for a time from the fibrous envelop of the kidney, but the total amount of hemorrhage was in no way alarming. The lumbar scar was reopened for drainage, and a rubber tube was led through it to the site of the kidney. The rents in the posterior and anterior layers of the peritoneum were then closed, and the wound in the abdominal wall approximated by silver wire and catgut sutures. On account of gastric irritation no fluid was introduced into the stomach during the following week, during which time nourishment was administered *per rectum*.

The amount of urine passed was as follows: First day, 8 ounces; second day, 20 ounces, and somewhat bloody; urea, 1.01 per cent.; specific gravity, 1020; third day, 49 ounces; fourth day, 88 ounces. After that it gradually subsided until the daily amount was 50 ounces, the urea being still below normal; though of greater amount than before operation. The patient recovered without incident. The extirpated kidney measured 9x5½ inches, and weighed 21 ounces. It was invaded by a tumor about as large as the fist, which was everywhere marked off by a distinct capsule. Microscopically it was found to be an adenoma. The patient remained well for a year when a recurrence took place from which he succumbed eighteen months after the nephrectomy.

CASE XXXVIII. *Sarcoma of the Kidney—Nephrotomy—Death.*—James L., aged seven years, was seen by me with Dr. J. B. Hunter, January, 1886. There was a history of failing health, some irritability of the bladder, but no hemorrhage or pus in the urine, though diminished urea was observed in a late examination. Three weeks before, his physician had recognized a swelling in the left upper half of the abdomen, which, when seen by me, was the size of a cocoanut, projecting downward to the umbilicus, very slightly movable, painless, and not at all tender. It could also be felt in the loin. A few days previously, an aspirator-needle had been introduced, and through it about one-half ounce of a slightly turbid deep yellow fluid and a little fresh blood had been withdrawn. It was hoped that a cyst or hydronephrosis existed, though his pallor and weakness were greater than should accompany such affections. Early in March a lumbar exploratory excision was made, but the repetition of aspiration on the exposed posterior surface of the enlarged kidney did not show any cyst. An incision was made into the soft mass, which appeared sarcomatous. The hemorrhage from the incision proved very troublesome, and by the time it was arrested no thoughts of anterior nephrotomy could be entertained. So much was the little patient weakened by the operative effort added to that of the disease, that he succumbed twenty-six hours thereafter. No autopsy was granted.

CASE XXXIX. *Carcinoma of the Kidney—Abdominal Nephrectomy—Death.*—Alexander P., aged fifty years, sent me by Dr. Ross of Montreal, entered St. Luke's Hospital February 27, 1891. The family history was unimportant, except that one sister died suddenly of cerebral tumor, and an aunt of cancer. Since 1888 the patient had suffered from indigestion with vomiting and slight jaundice, growing gradually worse with slight loss of flesh and strength. The year previous to admission, he had noticed a fulness on the right side of the abdomen accompanied by some pain, and the presence of a tumor was determined by several physicians. There were no urinary symptoms. The urine was acid, of a specific gravity of 1024, and contained a trace of albumin, but no sugar. In the sediment were a few leucocytes. The swelling in the right side was found to lie partly behind the distended colon, and a diagnosis of retroperitoneal cyst, probably connected with the kidney, was made.

March 2, 1891, the abdomen was opened by an incision along the outer margin of the right rectus muscle and a heart-shaped tumor exposed, which was adherent to the omentum and intestines.

The adhesions were separated, and the posterior peritoneum which covered it was divided. In the attempt to peel off the peritoneum to attach it to the anterior abdominal wall, and thus close off the peritoneal cavity, the tumor was ruptured, and about one quart of greenish inodorous fluid escaped in among the intestines from a cyst of the kidney. The cyst and kidney were removed after ligation of ureter and blood-vessels. A lumbar incision was made for a drainage-tube, and the abdomen closed, after cleansing and uniting its posterior divided layers.

The patient stood the operation well, but died within eight days of suppurative peritonitis. The kidney was found upon examination to contain a large cyst about five inches in diameter, from the wall of which projected masses which microscopic examination showed to be cancerous. The substance of the kidney itself was nearly normal.

METHOD OF OPERATION.

The lumbar incision as described in the cases cited, that is to say, a cut extending from the twelfth rib downward parallel to the edge of the quadratus lumborum muscle, and then, when near the ilium, curving forward as far as the anterior superior spine, or further if necessary, is, on the whole, the most satisfactory of the various incisions I have employed. Its length forward enables the operator to meet promptly accidents and complications. This incision is called König's, but is also claimed by Ancona. The muscular layers of the anterior portion of the incision are divided rather than separated, as has been suggested by Abbe, until the peritoneum is reached, and then the surgeon will have free access, not only to the kidney and its vessels, but also to the ureter, etc. The value of such an incision was well illustrated in Case XVIII., in which a torn vena cava was promptly recognized and sutured without difficulty.

The success previously alluded to (obtained in my last ten nephrectomies, performed during the past two years with but a single fatal result, and the last six of which

were consecutively successful) I largely attribute to the complete view of the operative field which follows even a freer extension of this incision anteriorly than in my earlier cases. The mortality, however, in the total of my twenty-five cases of nephrectomy herewith presented, is twenty-eight per cent.; which is only slightly better than the percentage in 180 cases recently presented by Tuffier, Israel, Newman, and Hamill, their mortality being thirty per cent. In their cases the lumbar incision was generally employed. Emphasis is again laid on the preference for division of the muscular layers of the abdomen; for though it is theoretically true that this separation of the muscles and their subsequent replacement affords a more solid wall, yet the usual method of carefully suturing in layers the divided abdominal fascia and muscles up to the vertical leg of the incision, and even a part of this if judgment so inclines, restores very happily the *status quo ante*. Moreover, in the comparatively few instances in which a certain amount of weakness and yielding of the cicatrix has resulted in a lumbar hernial bulging, it has usually shown itself in the vertical scar, that is to say where the drainage gauze had been left; and in none of these instances has the patient expressed any discomfort or inability from the weakness of the abdominal wall. Inquiry has been particularly made upon this point, as reference to the cases will show.[1]

For the removal of large tumors the anterior abdominal incision along the outer edge of the rectus abdominis muscle has been occasionally chosen. This is usually carried out as in ordinary abdominal work; but sometimes, when it has been revealed, as in Case XXXVIII., that a cyst is associated with the neoplasm, and once when an abscess was included in a tumor, the divided posterior edges of the peritoneum were attached at numerous points to that of the abdominal wound, thus shutting off the peritoneal cavity, and the extirpation of the diseased kidney accomplished by the so-called transperitoneal method. Anterior or abdominal nephrectomy is known to be more dangerous than lumbar, but it allows, of all operations, the best access to the vessels, etc., though since the increased prolongation forward of the lumbar incision, the anterior route with me has ceased to be employed. The difference in mortality of the two methods, lumbar and abdominal, has been given by Tuffier as twenty-eight per cent. in the former, and thirty-six per cent. in the latter.

For exploring the kidney or ureter for a suspected calculus, a few details may properly be discussed. The liberation and separation of such kidneys, particularly if not enlarged by abscess, may be accomplished, especially on the right side, so freely that the affected organ can as a rule be brought into and even out of the wound to allow careful palpation, and if exploration with the finger be decided upon, as it should be rather than relying upon untrustworthy prodding with needles, the pedicle of the kidney may be slipped between the second and third fingers of the left hand which will at the same time not only support and hold steady the kidney but facilitates compression of its vessels, so that when the exploratory incision is made into its substance to reach the pelvis with the introduced finger and sound, but little bleeding will occur. Usually the hemorrhage is not severe, even when compression is not employed; but I have once, under such circumstances, been compelled to plug the wound and postpone further examination for three or four days. At the close of such an exploration, with or without the extraction of a calculus as the case may be, it is my custom to pack the renal pelvis with a wick or string of iodoform or sterile gauze, and to suture the kidney wound with deep catgut stitches except at the point of exit of the gauze.

This same lifting-out of the kidney renders possible the better use of the X-rays for the detection of small calculi, as has been lately suggested by Fenwick, and already alluded to under "renal calculus."

The examination of the ureter for a moderate distance is easy by the operative incision described above. This will permit its palpation for two or three inches below the crest of the ilium. Internally the ureter may be examined through the incised kidney. When the lower end of the latter is strongly tilted or pulled up, by a ligature passed through it a flexible steel probe may be introduced and pushed through the whole length of the ureter. This requires a probe much longer than is anticipated. I have lengthened my own probe (after a number of trials) to twenty-three inches. It requires from nineteen to twenty-three inches of the probe to reach the bladder from the loin incision. Only once have I been able to feel the probe end in the bladder by means of a sound introduced through the urethra, though in a number of instances it has been passed to its full length. The advantage of a metallic instrument in the detection of a calculus is evident, as well as is its greater ease of introduction. It is, however, not easy to pass such an instrument into the ureter in all cases. One cannot always find the ureteral orifice in the renal pelvis. For help in this endeavor, I employ open-ended catheters of various curves (Fig. 1), through which, when introduced into the kidney pelvis, the flexible probe is carried and swept about in search of the desired outlet. When the probe is engaged in the canal, the catheter is slipped over its distal end and removed, and the probe is gently pushed onward. The length of the ureters, from the pelvis of the kidney to the bladder, varies from 26 to 34 cm. (10 to 14 inches) according to Huntington and to Funkel,[1] but the ureters are easily stretched. On exploration, when the ureters were normal, I have often found the length above given to be exceeded by reason of this extensibility, which is brought about by the resistance offered to the passage of a probe, even though flexible, through these doubly curved tubes.

When a cyst or cavity is a large one, turning the dilated and thinned kidney inside out as was done in Case XXV., will aid in finding the ureteral opening. The difficulty is sometimes great in appreciating an obstacle in the ureter, and one should, before condemning a kidney to extirpa-

[1] Since the above was written Dr. A. McCosh exhibited, at a meeting of the Surgical Society, a patient with lumbar hernia following nephrectomy, which, emerging from the vertical portion of the incision through an opening one-half inch in diameter, gave great discomfort and demanded surgical interference.

[1] *Deut. med. Wochenschr.*, April 29, 1897.

tion, either open the pelvis for exploration, either digital or otherwise, or pass a catheter from the bladder to the kidney (Albarran); or, as I propose doing in my next case, incise the ureter fairly low down in the lumbar wound, and from this point of entrance explore the kidney.

In ligating the renal pedicle the ureter is separately secured with fine catgut, and commonly the vessels are tied *en masse*. Strong silk is used in preference to thick catgut, the sterilization of which is often doubtful. Lately, care has been taken to employ a method which will permit the withdrawal of the ligatures from the third to the seventh day after the operation, as may be determined upon. To this end is followed either the plan of Cleveland[1] of enclosing in the ligature the wire loop of a galvanocautery, or that of Grad[2] of placing in each turn of the knot a releasing pull-thread. I have employed each of these contrivances with the happiest results, preferring, however, the latter for its simplicity.

I also venture to call attention again to the temporary packing of the large cavity left after a nephrectomy. (See Case XXV.) This not only controls the hemorrhage very well but drains most efficiently. The central packing is removed within from twenty-four to forty-eight hours,

FIG. 4. FIG. 5.

Fig. 4.—The liver and right kidney seen from the front. (Cunningham.)
Fig. 5.—A profile view of the liver and kidney. (Cunningham.)

and the exterior layer, constituting the Mikulicz bag, comes away on traction before the ligature is removed. In all renal operations anesthesia by ether is preferred to that by chloroform, as the latter has been fully shown by my own observations, as well as by those of others, to affect the kidney more seriously than does ether.[3]

A final word on the subject of the detection of renal enlargement. A long experience has convinced me that when, on the right side particularly, the kidney can be palpated on bimanual examination, it is either an enlarged kidney or a movable one. If the latter, beside the usual means of displacing and replacing it, it is always advisable to put the patient in an erect posture, resting the hips against the edge of a table, and then leaning forward with the hands or head against a support. This relaxes the abdominal walls and permits an easy repetition of the bimanual test. In all varieties of renal and gall-bladder enlargements, etc., I have frequently had much success in placing the patient in a sitting posture, in bed, leaning forward, with the hands clasping the legs above the ankles, which similarly relaxes the abdominal walls, and allows the surgeon's hands to pass well backward beyond the edges of the ribs, and well over the under surface of the liver.

In confirmation that a normal kidney is not to be felt anteriorly below the liver, I ask attention to the accompanying diagrams (Figs. 4 and 5) of results obtained by Professor Cunningham of Dublin.[1] Here it will be seen that such a small portion of the kidney projects below the liver as to be only rarely palpable. The recent investigations of Brewer also confirm this statement. Myles, in the article just quoted, also shows clearly the risk of probing a kidney of normal size or only one moderately enlarged through the skin; for there is risk, not only that the needle may perforate the peritoneum, but that a vessel or intestine may be punctured.

MEDICAL PROGRESS.

Two Cases of Sarcoma Cured without Operation.—OWENS (*New Orleans Med. and Surg. Jour.*, July, 1897) reports two cases of sarcoma of the leg below the knee in which complete cure followed injections of the mixed toxins of erysipelas and the bacillus prodigiosus. Sixty-three injections were employed in each case, the smallest dose being one-half a minim and the largest 10 minims. In one case, the diagnosis was confirmed by a microscopic examination, the tumor being a giant-celled sarcoma of the tibia following a contusion.

The Disappearance of Warts.—ROUSSEL (*The Med. Press and Circular*, November 3, 1897) takes up the question of the disappearance of warts and mentions a great number of instances, undoubtedly accurate, in which warts have disappeared within a few days after the application of the most ridiculous remedies, such as the liver of the male goat, the skin of a serpent, the soles of old shoes steeped in wine, rancid bacon, salt water, etc., etc. According to this writer, the theory of suggestion is the only one which will explain the disappearance of warts immediately after such varied treatment. Bonjour employs suggestion with intention, making a few cabalistic passes and telling the patient that the warts will disappear. Thus far, his prediction has never failed. The word suggestion does not reveal to us the intimate mechanism of the nervous centers, but it is sufficiently clear to be understood by all medical men. That an impression of a psychic order can bring about a durable anatomic modification of the papillary bodies is of extreme interest to all reflective minds.

THERAPEUTIC NOTES.

Vulvovaginitis in Children.—COMBY (*Jour. de Méd. de Paris*, October 3, 1897) says that the vulvovaginitis of little girls is almost always of a specific character, but almost never of venereal origin, being acquired in an inno-

[1] Myles, *op. cit.*

cent manner from towels, sponges, etc. External application of small douches are not sufficient to meet the indications. It is necessary to employ prolonged irrigations through a small flexible catheter or tube; for instance, a quart or more of a strong antiseptic solution, such as corrosive sublimate, 1–10,000 or 5000, permanganate of potash, 1–4000 or 2000, or even 1–1000. With a weak antiseptic solution it requires from two to six months to cure a vulvovaginitis. With a strong solution this may be accomplished in fifteen days. If the affection is very intense, the irrigations should be made three times daily, and as improvement is manifested the number may be reduced to two each day, one a day, one every two days, twice a week, etc. In simple vulvitis strong injections will do no good. The only treatment required is to bathe the vulva with plain boiled water, or a weak solution of boric acid, two or three times daily, and to powder the parts, or to smear them with some hydrophilic ointment.

In all cases the toilet of the diseased parts should be most carefully directed, and the possibility of the conveyance of the contagion to other children should be kept in mind. The general health of the patient will also require attention.

Treatment of Enuresis.—MARTIN (*The Med. Press and Circular*, December 15, 1897) gave a boy, aged seven years, who for some months had been in the habit of wetting his bed three or four times each night, the following mixture:

℞	Potass bromid.	ʒ ij
	Tinct. belladonnæ	ʒ ij
	Tinct. chloroformi co. . . .	ʒ j
	Aq. ad.	℥ vj.

M. ʒ ss. at 4 P.M., and a second dose at bedtime.

From the time when this was first administered there was no recurrence of the enuresis. The patient, in this case, was an active-brained boy, of athletic disposition, who was keenly alive to the desirability of overcoming his habit, but who had been unable to do so in spite of all endeavors. There was no phimosis, no adhesions, and no collection of matter beneath the foreskin to explain the constant recurrence of the affection. There were no symptoms referable to the bladder, no history of worms nor intestinal irritation, and the patient was not accustomed to lie on his back. The source of the mischief seemed to be in the direction of some form of cerebral excitement. The cure was perfect up to the time of report, about one month after the medicine was first given.

Treatment of Tuberculous Cystitis.—BANZET (*Centralb. für die Gesammte. Ther.*, November, 1897) recommends irrigation of the bladder with corrosive sublimate solution in cases of tuberculous cystitis. In his experience remarkable results have followed the use of this treatment, although he does not pretend to explain exactly how they are produced. Other antiseptics employed for a similar purpose, such as iodoform, lactic acid, sulphate of copper, formaldehyd, carbon dioxid, creosote, etc., have not given, in his hands, equally good results. The sublimate is used at first in a solution of 1 to 5000, and only after a considerable time is the strength increased to 1 to 4000, or even to 1 to 3000. A rapid increase in concentration may produce pain and hemorrhage. Thirty-nine patients were treated in this manner, and of these he considered six as entirely cured. Injections of guaiacol also gave good results. They have an anesthetic influence upon the mucous membrane of the bladder which is very grateful to the patient. If the pain cannot be relieved by medical measures, operations are necessary, of which suprapubic cystotomy, peritoneal drainage, and curetting may be mentioned. Curetting the neck of the bladder in a male may be performed through a minute perineal opening, and in the female through the urethra. This slight operation associated with subsequent drainage often produces remarkable relief. This method of treatment is preferable to suprapubic cystotomy in these cases.

There are, from a bacteriologic standpoint, two classes of cases of tuberculous cystitis. Those in which a great many bacilli are found in the urine, and those in which very few are found, or, possibly, no micro-organisms at all. Therapeutically, cases of the latter form are much more easily influenced by injections of corrosive sublimate. These may be cured in a short time. However, in the more severe forms the disease may be brought to a standstill, or even cured under favorable conditions. Naturally, general should be combined with local treatment.

Difficulties of the First Dentition.—In troubles due to teething, CHOMPRET (*Rev. de Therapeut.*, December 1, 1897) recommends that the mouth be frequently washed from early infancy up, with a solution of chloral hydrate, one per cent., an analgesic and antiseptic preparation with only feeble toxic power. Pruritus may be allayed by frequent rubbing of the gums with the following mixture:

℞	Cocain hydrochlor. . . .	gr. ij
	Chloroformi	gr. xv
	Glycerini	ʒ v
	Aq. rosæ	gtt. vj.

For coryza, the nose should be irrigated with a lukewarm solution of boric acid or chloral hydrate. If the gums are distended they should be lanced. If necessary, tonic treatment should be employed.

Preventive Treatment of Alopecia.—DEICHLER (*La Méd. Moderne*, November 6, 1897) points out the need of the organism of gelatinous and colloid substances if the hair and nails are to be kept in a healthy and active condition. He prescribes, for those of his patients who are troubled with premature loss of hair, soups made of the bones of young animals, or of commercial gelatin which contains gelatinous matter from the fibrous as well as the osseous tissues. When the patients have taken these articles regularly for a few days there is a noticeable change in the condition of the hair and nails. The nails become clearer and smoother, and the hair becomes stronger and shows less tendency to drop out. With this general treatment should be combined local treatment of the scalp, and, in the opinion of this author, frequent washing of the head with soap is one of the most useful procedures.

SATURDAY, FEBRUARY 12, 1898.

THE NEW YORK CITY BOARD OF HEALTH AND THE MEDICAL PROFESSION.

AT a recent meeting of the Medical Society of the County of New York the question whether midwives should be educated and licensed or abolished was presented for discussion. Finally a resolution was offered demanding that a bill be introduced in the Legislature which would "wipe out" the guild of midwives, whereupon one man had the insight and the courage to rise and insist that by the endorsement of such a resolution the Society would simply make itself ridiculous not only in the eyes of the community but of the entire State of New York. This warning appealed to the good sense of the Society, and the resolution was voted down.

At the present time there is a bill before the Legislature restricting the powers and acts of the New York City Board of Health. It is to be regretted that some one has not the foresight and the courage to declare with convincing force that the provisions of this bill are designed to make the profession of New York City ridiculous, not only in the eyes of the local profession, but also of the entire country. He who stands in the way of progress in these latter days, sooner or later is overthrown, and the wise course for the medical profession is to regulate and direct progressive forces when possible rather than endeavor to obstruct and suppress.

It has long been recognized and deplored that there does not exist in this country a scientific, disinterested, authoritative, governmental department of medicine whose duty it should be to declare officially the remedial efficiency of new drugs, to test the quality of all pharmaceutic and bacteriologic preparations, and so guarantee to the physician the efficiency of the agents constituting his armamentarium. Quietly, unostentatiously, almost unconsciously, there has grown up in our midst just such an authority, controlled and animated by a true scientific spirit, free from bias and personal aggrandizement. Clearly reference is here made to the New York Board of Health. The quality of the work done in its laboratory is recognized by all scientific men as of the first order. It has not only enabled the profession of New York to have at its disposal the best facilities for ensuring the bacteriologic diagnosis of diphtheria, but has also placed in its hands the best antidiphtheritic serum to be had anywhere in the world. It has not only kept abreast of the most advanced scientific ideas but in many instances has been the leader. As a matter of fact the first diphtheritic serum which was manufactured in this country was produced at the laboratory of the New York City Board of Health. With a most commendable conception of its duty to humanity it opened the doors of its laboratory to representatives from other boards of health throughout the country and to employes of firms which have now become producers of bacteriologic products. It thus appears that the New York Board of Health has been a school of instruction from which knowledge of modern bacteriologic methods has been disseminated all over the country. It has also steadily kept before it the fact that serum-therapeusis is still in the experimental stage and offers unlimited opportunities for improvement. By means of carefully conducted experiments the quality of antitoxic serum was steadily improved in its laboratory until it actually surpassed that made in any other laboratory in the world.

It can be said, without danger of contradiction, that diphtheria antitoxin, which is now accepted the world over as a specific in diphtheria, would certainly not have been used in this city or State to anything

like the extent it is now employed had it not been for the pioneer work of the New York City Health Department. All the producers of reliable antitoxin in this country are directly indebted to the laboratories of this Department for assistance in the production of this remedy, if, indeed, they are not wholly dependent upon it for the instruction and encouragement they received there. The virulent cultures which were obtained by this Department were sought by all biologic laboratories, not only in this country, but even by those of England, France, and Germany. Not only has this laboratory thus surpassed the laboratories of the world in procuring the best grade of diphtheria antitoxin, but it has improved by its investigations the quality of vaccine lymph and the methods of its preservation. With the glycerinated vaccine pulp now employed by the Board of Health such results are obtained in primary vaccination as surpass all previous experience. In more than 20,000 primary vaccinations made by the employes of this department during the past year, and which were subsequently inspected, nearly ninety-nine per cent. of successful results were obtained. As to the propriety of the Department undertaking this work, it may be said that vaccine virus is produced by or directly under the immediate supervision of the government in Great Britain and every other country on the European continent. There is no other producer of vaccine virus in New York State.

All antitoxins other than diphtheria antitoxin are as yet largely experimental. No commercial house can afford financially to undertake and carry on such experimental investigations as are necessary to determine the methods of production and the value of the efficiency of such unstable products. They will produce and offer for sale only such preparations as are profitable to them directly or indirectly, and as there are only three producers of diphtheria antitoxin in this country, the probabilities are that if the New York City Board of Health is restrained from manufacturing this product the price will soon be placed at such a figure as to be beyond the reach of all except the very rich.

More might be said in justification of the high estimate we have placed upon the work of the New York City Board of Health: of its production of streptococcic and tetanus antitoxins; of its thoroughly systematic and scientific methods of controlling the spread of pulmonary tuberculosis; of its high position as an authority in pronouncing upon the quality of biologic products manufactured in other laboratories, and, finally, of its superb results secured in reducing the death-rate in the city of New York to a percentage unparalleled in its history. Is it not the duty rather of the medical profession of this city, of the State, and, indeed, of the entire country, to encourage and maintain the permanent establishment of this magnificently organized institution?

The feature of the bill now before the Legislature which appeals universally to the medical profession is the clause removing a political disability from members of the medical profession, *viz.*: the inability under the old law for a member of the medical profession to hold the position of president of the Board of Health. This political disability was an indignity offered to the medical profession which all with justice resented, and, therefore, gave cordial approval to a measure which restored medical men to a political equality with their fellows. But attached to this bill there have crept in numerous modifying clauses as riders, which, if enacted into law, will so cripple the Board of Health as to incapacitate it for a continuance of the work which, as we have said, has called forth not only the admiration of this community, but of the world.

Is it not, therefore, the duty of the medical profession to cast its powerful influence against this bill and so witness to the community that they are ready, as ever, for the benefit of humanity, to carry preventive medicine to the very fullest limit justified by modern science.

SOME CONSIDERATIONS OF THE BILL RESTRICTING THE POWERS OF THE BOARD OF HEALTH.

THE framers of this bill, by one of its provisions, assume to determine for all time what diseases shall be regarded by the sanitary authorities as infectious, contagious, or pestilential, and in so doing have excluded such diseases as the plague, relapsing fever, puerperal fever, tuberculosis, leprosy, contagious influenza (*la grippe*), epidemic dysentery, and all the contagious diseases of the eye and skin.

Under the provisions of this bill the Department of Health of New York would be powerless to act (until special legislation was obtained) in the pres-

ence of an epidemic of relapsing fever, or the introduction into the city of the bubonic plague from the East, which is possible at any time.

The chief purpose of the provision specifying what diseases should be regarded as contagious or infectious is to exclude tuberculosis or consumption from the list of the diseases over which the Health Department has power to exercise supervision; yet the contention that tuberculosis is not infectious is limited to a few, and the statistics of the world show that it destroys more lives than all the other infectious diseases combined. Nearly one-seventh of all deaths throughout the civilized world are due to tuberculosis, and nearly one-fourth of all deaths among the adult population are due to this disease, and yet the framers of this bill would exclude this scourge from the possibility of supervision by the sanitary authorities.

The provisions of the present law as now enforced can in no wise work a serious hardship to the unfortunate sufferer from the disease, and the enforcement of its provisions, it is believed, will be followed by a marked diminution in the number of cases of this affection in New York.

The sanitary authorities under the present law require that all cases of pulmonary tuberculosis shall be reported to the Health Department, and that to prevent infection measures shall be taken to render the sputum of such patients harmless. No inspection is made in cases under the care of physicians. Those who are too poor to employ a physician are visited by inspectors of the Health Department and printed instructions as to the methods of preventing infection are left with the patient and his family. The Health Department is also empowered to provide hospital accommodations for such patients as are too poor to obtain medical aid, and whose condition and environment require that that they should receive such assistance. There are turned away from the general hospitals in this city each week from fifty to seventy cases of pulmonary tuberculosis chiefly because of lack of accommodation in these institutions. It is to provide for such as they that the Health Department has received during the last year $60,000 from the municipality. This is to be expended for the care of patients admitted to various institutions at the request of the Health Department and who cannot be provided for in the various public hospitals. This bill would prohibit the Department of Health from assisting in any way in the care of these persons.

The assertion has been frequently made that it is the intention of the sanitary authorities to isolate and segregate from the community cases of pulmonary tuberculosis, and to provide special hospitals for the accommodation of patients suffering from this disease, these hospitals to be under the care of the Health Department, and the treatment to be directed by its officers. The sanitary authorities have frequently denied that such is the purpose of the Health Department, and have repeatedly stated that they do not propose to carry out any such plan. It is their purpose to educate the public whose interest is the greatest to prevent the spread of pulmonary consumption, so that they may be enabled to carry out the simple measures necessary to accomplish this, and they do not propose to establish special hospitals under the management of the Department. That the present law and the methods used to enforce it have the sympathy and approval of the public and of scientific medical men, cannot be doubted. No sufficient argument has yet been advanced to show the necessity of the proposed changes in the law. The bill now under consideration, if enacted into a law, would remove the safeguards aimed to prevent the spread of consumption in New York, and this the people will justly resent.

THE BRITISH MEDICAL COUNCIL.

VICTOR HORSLEY has been recently elected one of the Representatives on the General Medical Council of Great Britain.

The General Medical Council is a sort of board of examiners and licensing, and is composed of eight members chosen by the medical colleges of England, eight by the colleges of Scotland, five by the colleges of Ireland, five nominated by Her Majesty, and five elected by the medical fraternity at large; the latter are known as direct representatives, and are, as a rule, chosen from among the general practitioners of the smaller towns. The members who represent the colleges are nicknamed "academic respectabilities," while those named by the Queen are called "their officials."

Horsley's election was a close one, his strongest

opponent being Michael Foster, the eminent physiologist.

The election is conducted by letter vote. In the present instance about 22,000 voting papers were sent out to the registered physicians of Great Britain and Ireland and a return requested within a certain time. Only 14,000 availed themselves of the opportunity. Several hundred ballots were ruled out because of improper marking, lateness, etc. Horsley received 7000 votes and Foster 6100; a few hundred were divided among the remaining candidates. While the General Council has very limited powers, the general practitioner looks to it for all sorts of things. According to one prominent medical journal the physicians regard it "as a kind of fairy god-mother whose business it is to provide silver spoons for her professional children, and to shield them generally from the slings and arrows of outrageous Fortune."

The Council provides for the entrance examination of students in medicine and examines them again before registering them as practitioners. Its real title is "General Council of Medical Education and Registration of the United Kingdom." Sir Richard Quain is its presiding officer.

It has only been a few years that the general profession has had direct representation in this council, and those who uphold the system are afraid that if in future elections so large a proportion of the profession abstain from voting as obtained in the present instance, the privilege will be taken away from them. Of the 22,000 voting papers distributed, 8000 (or considerably more than one-third) were not returned. The election occurs once in seven years; the present election was made to fill the unexpired term of a member who had resigned.

ECHOES AND NEWS.

Exsection of the Stomach.—Unsuccessful attempts have been made by surgeons in St. Louis and Wilwaukee to repeat the operation of total excision of the stomach, which was successfully carried out by Dr. Schatter of Zurich.—*Science.*

The Dispensary Bill.—The Senate Committee on Public Health has reported favorably on the Dispensary Bill introduced by Senator Sullivan in the New York Legislature. One amendment to it was made, providing that the action of the State Board of Charities may be reviewed by the Supreme Court of the State.

New Editor of the British Medical Journal.—At a recent meeting of the Council of the British Medical Association, the assistant editor, Dr. Dawson Williams, who for seventeen years has been connected editorially with the journal, was unanimously appointed editor. Mr. C. Louis Taylor, who has been sub-editor for the last eleven years, was appointed assistant editor.

Epidemics at Barre, Vt.—The news comes from Rutland that 170 cases of diphtheria and 130 cases of typhoid fever have been reported in Barre, Washington County, which has a population of only 4000. A large number of deaths have occurred. The State Board of Health is making an investigation as to the cause of the double epidemic.

"Faith Cure" in Indiana.—Advices have been received from Indianapolis that warrants have been issued for the arrest of "Dr." J. L. Stevenson and Samuel Fuller, leaders of the "Christian Scientists" in Jackson township, on the charge of manslaughter. They are held responsible for the deaths of a child of the former and the wife of the latter, both of whom died without receiving medical attention.

The Voluntary Determination of Sex a Proprietary Idea.—It is reported from Vienna that Professor Schenk has prepared a paper in which he describes his system for determining the question of sex. The rights to publish this pamphlet have been sold in Germany for $10,000. There is a stipulation, however, that it shall not be published until the American and English rights have been disposed of.

Hospital Sued for Damages.—According to a decision recently rendered by Justice Goldfogle in the Fifth New York District Court, charitable institutions are not responsible for damages which may be inflicted by their agents and servants. A suit in which this decision was rendered was brought against Roosevelt Hospital, New York, by a man whose bicycle was demolished by an ambulance belonging to that institution.

Plague Measures in Bombay.—Recent despatches from India say that quarantine barriers are being established in all the towns against the Bombay exodus. The Governor, fearing that the plague will increase rapidly within a few weeks, and that the penning up of the large population will result in a panic, has issued an order inviting those affected to remove themselves and their families to a camp on the islands across the harbor. Regiments have been ordered to Bombay for plague duty.

Register of Licensed Physicians Practising in Illinois.—The twentieth annual report of the Illinois State Board of Health to be published soon will contain an official register of all licensed physicians practising in Illinois. The secretary of the Board, Dr. J. A. Egan, in order to ensure accuracy, requests that every physician entitled to the privilege who desires his name and address correctly reported to send the information to him on a postal-card at once, mentioning number and date of certificate.

Radical Treatment of Smallpox at the Immigration Bureau.—A case of smallpox was recently discovered in the detention quarters of the Immigration Bureau at New York.

The patient was a Russian, who arrived on January 22nd from Rotterdam. He was at once sent to the Riverside Hospital, and the detention-room, articles of clothing and bedding were fumigated, and the ninety other detained immigrants and those of the employes who had come in contact with the patient were vaccinated.

Indian Plague Riots.—Recent news from Bombay indicates the steadily advancing increase of the bubonic plague. The superstition and opposition of the native population are serious bars to the application of sanitary measures. In the neighborhood of Bombay fatal riots have been occasioned by the efforts of the health authorities to prevent the spread of the disease. The rioters have killed a hospital assistant, burned the segregation camp, wrecked the post-office, and cut the telegraph wires.

Professional Opinion Regarding the Board of Health Bill.—It is gradually becoming known that a strong, intelligent branch of the profession of New York is opposed to the Brush Bill now before the Legislature. Evidences of this are rapidly becoming apparent. Dr. Jacobi has placed himself upon record as opposed to the bill by resigning from the Special Committee of the County Medical Society appointed to consider the bill. Resolutions in opposition to the measure have been unanimously passed by the visiting-staffs of Bellevue, New York, Presbyterian, Roosevelt, and St. Luke's Hospitals, and the Hospital for Contagious Diseases.

The New Philadelphia Health-Officer.—Dr. Benjamin Lee secretary of the State Board of Health and of the State Quarantine Board, was recently appointed by the Governor Health-Officer of Philadelphia, to fill the vacancy caused by the resignation of Theodore Stulb. Dr. Lee was graduated from the Medical Department of the University of New York in 1856, and formerly resided in this city, but removed to Philadelphia in 1866. He is widely known as a specialist in orthopedic surgery, nervous affections, and mechanical therapeutics. He introduced the method of self-suspension in the treatment of spinal affections, and has contributed many valuable papers on the special departments to which he has given time and study as well as to the science of public health.

The Society of the Alumni of Charity (New York City) Hospital.—The eighth annual reunion and banquet of this Society was held at the Savoy Hotel, New York City, on the evening of February 2, 1898. From a social as well as a gastronomic standpoint, the gathering was a most delightful affair. About 150 covers were laid, and some of the members journeyed many miles in order to be present. In addition to the usual postprandial speeches and good stories, the Society indulged in the unusual experience of listening to a serious discussion of the dispensary question by the Reverend Dr. Greer. In response to the circular letters which were sent out asking for personal information, 150 answers were received, from which it is learned that 25 of the alumni are now either professors or instructors in medical schools, 6 are authors of standard books, and the writers of articles for medical journals are as numerous as the members themselves. Some of the members were found located as far north as the Klondike and others as far south as South America. They are scattered through twenty-two States of the Union; one alumnus is located in Japan and one in China. The following officers were announced for the ensuing year: President, Walter B. Johnson; vice-president, W. L. Stowell; secretary, Charles J. Proben; treasurer, Henry M. Schroeder; editor, A. T. Muzzy.

The Status of the Marine Hospital Service as a National Quarantine Board.—The Senate Committee on Public Health and National Quarantine, in its report on the Senate bills concerning a national quarantine submitted to it, says: "It has not been satisfactorily shown that the yellow fever which entered the United States last summer at a point on the Gulf coast near Ship Island occurred by reason of the carelessness or negligence of the officers on duty at the Ship Island Quarantine Station. The fever first appeared at Ocean Springs, a few miles from the Station, but it is unjust to conclude on the ground of propinquity alone that it came through Ship Island. In our opinion it is wise and necessary to retain the present system of quarantine under the management of the Marine Hospital Service, with its hospitals, quarantine stations, improved apparatus for the investigation of disease germs, and corps of officers, twenty-five per cent. of whom have experience in the prevention and treatment of infectious diseases, and especially of yellow fever. It may be found expedient hereafter to expand the service into that of a department, but to do so now would mean the useless expenditure of money and the destruction of the only systematic antagonism to the invasion of contagious disease. While we believe that the quarantine jurisdiction of the Marine Hospital Service should be retained, we are clearly of the opinion that its powers should be enlarged and made more distinct and uniform. No timidity nor adherence to technicalities should prevent the adoption of any measures which are necessary to exclude contagious diseases from our shores. The experience of past years, and especially of last summer, demonstrate the absolute and immediate necessity of so amending existing laws as to enlarge and concentrate the powers of the Marine Hospital Service, so that the present sporadic and conflicting condition, in which there is constant friction and collision between Federal and State officials, shall be changed, and the exclusive, ultimate control be given to one authority."

The Source of the Yellow-Fever Epidemic Definitely Determined.—The committee of the Mississippi Legislature appointed to investigate the yellow fever of last summer has made its report, after having visited Ocean Springs, Biloxi, and other coast towns where the fever prevailed. It finds, beyond all question, that the yellow fever originated at Ocean Springs, Miss., but not from the United States Marine Hospital Quarantine Station at Ship Island, as was supposed, and it also declares that that quarantine station is not a menace or a danger to the health of the people of the Gulf Coast or of the South. Those who did not think that the fever originated at Ship Island, and was communicated by the quarantine officials to the mainland, held

that it was introduced by Cuban refugees who met at Ocean Springs in June to arrange for a filibustering expedition to Cuba, and one of whose members died of a mysterious disease and was buried at Ocean Springs. This very generally accepted theory is disproved by the Mississippi legislative committee, which finds that yellow fever was introduced into this country much earlier than it was supposed—as early, indeed, as April—and that it came, not from Cuba, but from Guatemala. The existence of yellow fever was not discovered at Ocean Springs until September 6th, and hitherto the utmost researches have not traced it back beyond the end of July. The committee finds that yellow fever prevailed during four months at Ocean Springs, and that it was introduced into this country by a Mississippi family, who had been temporarily in Guatemala and who came to the United States on the Central-American steamer "Breakwater." Their baggage was neither fumigated nor disinfected, and they went direct to Ocean Springs, where one of them was taken sick with fever. Within a few days other cases of fever appeared in their immediate neighborhood, and from that time a disease of the same character prevailed at Ocean Springs until the end of the summer, although it was not diagnosticated as yellow fever until September. The committee attributes the introduction of the yellow fever to the fact that the quarantines of the Gulf States against the West Indies and Central America go into effect on May 1st, whereas the "Breakwater" brought the disease into the country in April—before the quarantine was put in operation. This shows the necessity for early quarantine in order to assure protection. The epidemic of 1878 was brought into this country long before the quarantine was put in force, the steamer "Emily B. Souder," which brought it, arriving in March. The committee also investigated the amount of damage done by the yellow-fever scare, and found it to be greater than estimated. The loss to business in the State during the prevalence of the scare was from twenty-five to forty per cent., and property on Mississippi Sound has shrunk 30 per cent. in value because of the fever. The expense of the various quarantines in vogue was found to run as high as $5000 in many of the counties.

CORRESPONDENCE.

PRIVATE DISPENSARIES.

To the Editor of the MEDICAL NEWS.

DEAR SIR: Before writing a word on the subject of this letter an apology is tendered to your readers. I write for information in regard to the small *flat dispensaries* springing up all over the East Side of this city. It appears that these places (one can hardly call them dispensaries) are run entirely as private affairs; in the sense that the physician in charge tries to turn each case officeward. He may be anxious for patients because he is connected with some large clinical institution and wishes to hand material to his professor for students to examine. Go through East Seventy-third street between Second and Third avenues and you will find the words "Dispensary, Walk In," in a window, but on the door it reads, "*Office, East Seventy-eighth street.* Again, try Eightieth street between First and Second avenues, or Eighty-third street between First avenue and Avenue A, or Ninety-fourth street, and many other streets, and see what games our very professional brethren are playing. District physicians find daily, bottles of medicine in the poor man's home without any doctor's name attached thereto, for which the patient has paid from 10 to 25 cents each. The composition of these mixtures is, as a rule, R. and S. Co., or aquæ crotonis, with, perhaps, some bitter added for flavor. Is there no law, legislation, or remedy which can save the ignorant classes from this species of medical fraud?

E. C. CHAMBERLIN, M.D.

NEW YORK, January 11, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

DISPENSARY ABUSE—THE TYPHOID SITUATION—THE COLLEGE OF PHYSICIANS' ATTITUDE TOWARDS FILTRATION OF THE WATER-SUPPLY, AND THE PLACARDING OF HOUSES BY THE BOARD OF HEALTH—LEGALITY OF THE COMPULSORY VACCINATION LAW CONTESTED—A SETBACK TO THE BAKE-SHOP REGULATIONS—REPORT OF CONTAGIOUS DISEASES FOR 1897—DR. W. W. KEEN—DR. FRANK HAEHNLEN—THAT $100,000 APPROPRIATION FOR THE JEFFERSON HOSPITAL—A BEQUEST TO THE PENNSYLVANIA HOSPITAL—DR. EVANS' WILL AGAIN.

PHILADELPHIA, February 5, 1898.

A SIGNIFICANT step in the movement to suppress "hospitalism" in this city was taken at a special meeting at the Charity Hospital on February 5th, to protest against the indiscriminate gratuitous treatment of patients by hospitals and dispensaries. Resolutions were adopted requesting the Philadelphia County Medical Society to confer with the Board of Charities and Correction and with the boards of managers of Philadelphia hospitals, with a view to adopting measures for the restriction of the evil. Dr. Frederick Holme Wiggin of New York City, read a paper on "The Abuse of Medical Charity in New York," and suggested that charitable institutions be placed under the strict control of a State board of charities. Addresses were also made by Drs. Horace Y. Evans, A. B. Hirsh, and others. The statements made by the several speakers at this meeting may be considered to voice the general sentiment of Philadelphia medical men on the dispensary question, which, with the multiplication of hospitals, has grown to be a matter of serious import. The present step is but an indication of what is soon to follow, for your correspondent is informed by reliable persons that the abuse is to be thoroughly ventilated, and that, as soon as the requisite data and statistics have been collected, a determined fight against the evil is to be made both by local discussion of the subject and by State legislation.

A comparative reading of this week's mortality report of the Board of Health shows that enteric fever is still prevalent in this city to an unusual extent, although it is gratifying to be able to state that the returns for the week reach a slightly smaller total than last week. There were 199 new cases of typhoid fever reported for the week just

ended (February 5th), with 16 deaths from this cause, as compared with 212 new cases and 10 deaths from the preceding seven days. In the nine weeks which have elapsed since the present outbreak, over fifteen hundred new cases, more than one hundred of which proved fatal, have occurred; and during the first six weeks of the present year almost eleven hundred new cases were reported. The chain of evidence presented by the report of Dr. A. C. Abbott, Director of the Bacteriologic Laboratory of the Board of Health, leaves no doubt concerning the pollution of the water-supply; although, as was expected, he was unable to demonstrate the presence of the specific cause of typhoid fever in the samples of water examined. The detection of the colon bacillus in some of the suspected water is direct proof that the Schuylkill water is polluted with excreta from the human intestinal tract.

At the last meeting of the College of Physicians of Philadelphia, February 2d, two topics of importance to the community at large, the immediate improvement of the city water-supply, and the obnoxious custom of placarding houses in which contagious diseases are present, were acted upon. Relating to the first, the following resolutions were unanimously adopted: "WHEREAS, The College of Physicians of Philadelphia believes that improvement in the water-supply is essential to the city's health, and even if a pure and ample source were at hand it can never be possible while the water is drawn from populous districts, to avoid all chances of contamination, nor to secure it without years of waiting; therefore, be it *Resolved*, That this college declares itself most strongly in favor of filtration of the city's water; that it believes that this should be done at the earliest possible moment, and to so much of the water-supply as money can be made available for. And further be it *Resolved*, That this college considers it unwise, undesirable, and dangerous to the conservation of the public health to permit such important municipal functions as the supply or filtering of the water of the city to be in the control of any body of men other than the government of the City of Philadelphia."

It is interesting to observe that the college has, in this latter paragraph, unmistakably recognized the fact that the control of Philadelphia's water-supply lies entirely in the power of a large clicque of politicians hostile to any reform, for reasons best understood by themselves, unmindful of the loss of life which daily adds to the monument of shame against them, and prostituting their pledges as representatives of the constituents electing them to office. A committee consisting of Drs. J. K. Mitchell, A. C. Abbott, and D. D. Stewart was appointed to present the above resolutions to the city Councils. The second topic, that of placarding with yellow signs houses in which contagious diseases are present, aroused much discussion on both sides, and gave rise to a good deal of caustic criticism of the methods of the Board of Health at present in vogue, while the board itself, came in for a full share of the college's disapproval. Dr. Arthur V. Meigs opened the subject with a paper, entitled "Reasons Why the Placarding of Houses in Which There Are Persons Suffering with Scarlet Fever and Some Other Contagious Diseases Should Not Be Continued." He declared that the custom of placarding houses is not only a source of great inconvenience, but even an inquisitorial interference with the private rights of families. He referred to the fact that in reality in many cases the non-enforcement of the law had made it a dead-letter, and he characterized the members of the Board of Health, with two exceptions, as being ignorant of the requirements of their office, mentioning, in passing, that their dereliction of duty was a matter of general admission. Dr. Meigs' statements were endorsed by many other Fellows of the college, and views concurring largely with his own were expressed by Drs. James Tyson, Henry R. Wharton, Morris J. Lewis, and others. Among those who deprecated the expression of extreme views in this matter were Drs. H. A. Hare, A. C. Abbott, and H. B. Pease, all of whom favored a more moderate view of the subject. The outcome of the discussion, during the course of which the methods pursued by the Board of Health were analyzed and criticised with no gloved hand, was the passing of a resolution appointing a committee, composed of Drs. S. Solis-Cohen, Wharton H. Sinkler, and F. A. Packard, to wait upon the Board of Health to represent to this body the opinion of the college on the subject under discussion, and to ask that the board discontinue the present custom of placarding all houses in which are cases of contagious disease.

The constitutionality of the Pennsylvania compulsory vaccination law is being contested in the Blair County courts of this State, where the local courts have issued a mandamus against the School Directors of the City of Altoona, requiring them to show cause why the children of the contesting party should not be admitted to the public schools of that city without a certificate of successful vaccination. The importance of the decision to be rendered in this case cannot be overestimated, for an endorsement of the present law in this test-case should effectually silence the protests of the antivaccinationists, and should show to their fellows in absurdity, the antivivisectionists and the faith-curists, that laws are laws, notwithstanding their many loud and hysteric clamorings for a revision of the statutes to suit their delusions.

Another law which has recently been contested on the grounds of its unconstitutionality is the "bake-shop law," which Judge Willson this week characterized as "meaningless and absurd," at the same time handing down an opinion quashing the indictments against three bake-shop owners charged with its violation. The "bake-shop law," which went into effect last summer, has already proved a valuable means for the control of the sanitary arrangements of bakeries and for protecting the health of the consumer and of the bake-shop employe, and it is hoped that Judge Willson's opinion will be speedily reversed by the Supreme Court, to which the Commonwealth will at once appeal. Pending this final decision, the State Factory Inspector, Mr. Campbell, has announced that he intends to continue to prosecute all violators of the law.

The report of Medical Inspector J. H. Taylor shows that during the year 1897 there occurred in this city 5031 cases of diphtheria, 3553 cases of scarlet fever, and

2994 cases of enteric fever, this being, as compared to the year 1896, an increase of 1840 cases of diphtheria, of 2511 cases of scarlet fever, and of 505 cases of enteric fever. Last year there was an increase of 369 in the number of deaths from diphtheria, an increase of 221 in deaths from scarlet fever, and a decrease of a single case in deaths from enteric fever. During the years there were 2388 deaths from pulmonary tuberculosis reported, or a decrease of 136 from the preceding year.

Dr. W. W. Keen, who has been convalescing at Cape May from his recent illness, has returned to the city, and expects to be able in the near future to resume his professional duties. Another medical man who has been on the sick-list is Dr. Frank Haehnlen, late of the Medico-Chirurgical College, who is again quite restored to health.

The doubt existing in the minds of the trustees of the Jefferson Medical College and Hospital as to whether a change in the building plans of the hospital of that institution would disbar them from the use of the State appropriation of $100,000 granted them last year, has been dispelled by the announcement of the State Attorney-General that the change may be made without invalidating the appropriation. The new site for the hospital, which the institution intends to erect during the coming spring, has not yet been definitely decided upon.

The Pennsylvania Hospital has been left the sum of $50,000 by the will of Josephine M. Ayer of Lowell, Massachusetts. If we mistake not, this Mrs. Ayer is the widow of the Ayer of sarsaparilla notoriety, concerning whom, however, comment is unnecessary, in view of the munificence of his relict.

The uncertainty regarding the bequest made by the late Dr. Evans to found a dental institute and museum in this city has been cleared up by the receipt of copies of the document by the mayor. The city authorities immediately took legal steps for the incorporation of a trust to execute the will, and an appropriation has been asked, under the terms of the will, to protect the city's interests by retaining counsel in Paris. Just how large the bequest is, has not yet been announced, but it is said on good authority that the sum is not far from $2,500,000.

The total number of deaths occurring in this city for the week ending February 5th, was 451, a decrease of 7 from last week, and a decrease of 54 compared to the corresponding week of 1897. New cases of diphtheria numbered 93, with 23 deaths; and of scarlet fever, 56, with 6 deaths. Of the total number of deaths reported 142 were of children under five years of age.

OUR PRAGUE LETTER.

[From our Special Correspondent.]

THE POLITICAL SITUATION AND THE GERMAN UNIVERSITY OF PRAGUE—PROFESSOR VON JAKSCH'S NEW CLINIC—MEDICAL OPPORTUNITIES AT PRAGUE.

PRAGUE, February 3, 1898.

DURING December the eyes of Europe were turned Prague-ward to observe the result of the race disturbances in the Bohemian capital. For awhile it looked as though vacillating Austrian policy would allow serious injury of life and property to be inflicted upon the Germans in Prague before stern military regulations would put an end to the rioting and wanton destruction. In the early days of December hostile Czechic mobs surged around the German University buildings. The handsome laboratories of the Medical Department especially attracted the attention of the thoroughly aroused populace. The buildings bore the hated name "German," and the mob, thoughtless of the good work which had been accomplished in them, set about their wanton destruction.

There was no question of opposition, the police for the time being were too few to be able to protect the endangered property, and the work of destruction went on almost unhindered. The chemic, anatomic, and pathologic institutes suffered most. Windows were smashed with stones, which went crashing through show cases in museums, ruining valuable specimens and preparations. The pathologic-Anatomic Museum of Professor Chiari especially suffered in this way. Not content with the damage already done the mob broke into the lower floors of some of the buildings and proceeded with their destructive work —the anatomic room of the professor of legal medicine was almost ruined.

For several days there were repetitions of the outrages. It was deemed advisable to dismiss the students of the German University Medical Department for the Christmas holidays early in December. A declaration of what was practically martial law and the hasty importation of Austrian troops from other parts of the Empire, brought the rioters to their senses. Collisions between the troops and the populace did not occur to any serious extent, and gradually the old town again became quiet. Every occasion was taken to make impressive demonstrations of the presence of additional troops, and with the desired quieting effect.

It is still considered advisable to place special guards around the German University medical buildings on holidays when the presence of large numbers of the working classes on the street might prove an occasion for further violence and destruction. In the early days some demonstrations were made by the mob before the houses of German professors, and in one or two instances these were such as to endanger the lives of the occupants. Professors Germak and Goldschmidt of the Medico-Legal and Chemic Departments being especially singled out, but on the whole the rising was distinctly racial in character and very little of personal animosity entered into it.

At Prague it is a tradition that the prominent men of a party suffer for the ideas of the party. The old town possesses the unenviable distinction of having two council-rooms, from the windows of which councillors have been, on two separate occasions, flung to destruction. On the whole the mixture of elements which compose the Prague populace are just such as are not prone to take counsel, but act first and think about it, perhaps repentantly, afterward. Everything now seems thoroughly quiet. The presence of the additional soldiers on the

streets is the only sign of the previous trouble. The German University reopened on January 10th, as usual.

The same day the diet of the Bohemian representatives for the province convened, and the last remnants of the martial law which had been allowed to remain in force up to that time was declared inactive.

The Czechs are fearful of losing, in the unsettled state of Austrian politics, the language rights so recently acquired by Austrian law, and are intent on making their feelings in the matter clear. The Czechish journals here in Prague have been fomenting racial discord, and a number of their issues have been suppressed.

For a while it seemed as though the German University might leave Prague for good. There are examples in history for such a course of action. The University of Leipzig owes its foundation to the withdrawal of German professors and students from the University of Prague nearly five hundred years ago, because the reigning king of Bohemia proposed to limit the privileges of foreign students attending the University. At a meeting of the representatives of German feeling in educational matters, held on the 28th of December last, it was proposed to transfer the present German University of Prague to Eger. Here, not far from the Bavarian boundary line, in the midst of a thoroughly German population, it was thought that it would regain its old prestige. It has gradually lost ground beside its vigorous young rival, the Bohemian University here, and under present circumstances many of the young Germans of Bohemia go either to Vienna or to one of the universities of Germany.

The expense of such a removal was an almost insurmountable obstacle. Generous offers were made, but universities are no longer, as in the olden days, merely a corps of professors and a body of students. Lecture-rooms, laboratories, hospitals, and libraries are now absolutely essential for teaching-purposes, and all these cannot be called up in a day, even when there are unlimited financial resources, which there are not—for educational purposes—in any place in Austria. Then too, to abandon Prague just now would look too much like abandoning their standards in the face of the enemy. So it is settled: the German University will remain here, and with the memory of the work which has been done within her walls, the medical world can only wish her the meed of success she so richly deserves.

Meantime, medical matters are not at a standstill. Professor von Jaksch's new clinic is being rapidly pushed to completion, and will probably be ready for partial occupancy by the time of the opening of the summer semester and entirely completed for the next winter semester. It contains some features, as might be expected since Professor von Jaksch himself has had a hand in the drawing of the plans, which seem worthy of special mention. Here in Prague, where the various contagious diseases may be expected to turn up at almost any time, owing to the unsanitary conditions prevalent, it is very necessary to guard against their introduction into the hospital wards. For all patients with fever who are admitted there is a reception ward in which they are observed for twenty-four hours, or until such time as it is absolutely sure what the condition really is. Everywhere one finds the glazed walls, the rounded corners, and the oiled floors, which admit of thorough antiseptic cleaning.

All the wards are so arranged that no beds are placed against the walls, and no patient faces the glaring light from windows directly in front of him, but has the light fal from behind. The large, high, airy, thoroughly lighted, and ventilated wards are much more suggestive of our American hospitals than one usually sees over here. There is, besides, a recreation and a retiring-room for nurses—a feature which is almost unique in German medical institutions, and a pregnant sign that they are beginning to realize that if they would have a better class of women as nurses they must take pattern after English and American ideas, and afford them better treatment than they are accustomed to receive.

It is typical of Professor von Jaksch, and of some of the methods he has been the means of introducing into practical medicine, that the laboratories in connection with the wards should be large, commodious, inviting rooms. For all the instruments of precision a special room, centrally located as regards the laboratories, has been erected. It has special walls arising directly from the foundations, with sliding-doors which will not slam, and with special arrangements in windows and doors to prevent the entrance of dust. It is hoped, thus by lessening vibration and preventing jarring, and to as great an extent as possible the presence of dust, that even hospital scales, polariscopes, spectroscopes, etc., will really be what is expected of them, instruments of scientific precision.

Prague as it is, with its large and varied clinical material, with a teaching staff that contains some of the great names in German medicine, and with its magnificent opportunities in obstetrics, is likely to remain for many years the Mecca of a good many foreign medical students. One cannot but think that many an American who comes abroad for medical studies misses the golden opportunities to be had in many a smaller university town because he comes with the idea that his studies must be most effective if made in one of the great capitals, where the harvest indeed is great, but the laborers are legion.

TREATMENT BY MOVEMENTS IN DISEASES OF THE NERVOUS SYSTEM—NEURALGIA CURED BY INJECTIONS OF OSMIC ACID—PROPHYLACTIC VALUE OF PERIODIC SWEATS.

GOLDSCHEIDER addressed the Union for Internal Medicine, December 13th, on the subject of *treatment by movements in nervous diseases*. He has applied the theories of Frankel and Leyden in the treatment of numerous tabetic patients, who are able to learn, by using what is left of their sensibility, and particularly with the help of their eyes and muscular sense, to perform many coordinated movements which has become impossible for them without this practice. Those patients who are already bedridden must begin with simple movements, and must be protected from overdoing, as they have no means

of knowing when their muscles are exhausted. The general nutrition must also be kept up as well as possible. When patients are still able to go about, the treatment should consist not so much in complicated motions like walking, but in very simple ones, such as touching with the toes a given point. No especial apparatus is necessary. The pauses between the periods of exercise should be long to avoid overdoing; and it is well to tone up the muscles at the same time with massage and electricity, and to bandage the joints with flannel, to prevent overextension. The speaker said that he had observed good results from this treatment in many diseases besides tabes. In the intention tremor of multiple sclerosis, which is really an ataxic symptom and is closely related to tabes, the effect of exercise is prompt. Here attempts are made to touch a certain point with the finger. The disease itself is of course not affected. In chorea, in writer's camp, and in different paralyses, improvement also follows these regular daily exercises.

KANN had tried the treatment in some thirty cases of tabes, and in three of muliple sclerosis, with excellent results. The requisites for success are patient and persistance on the part of both doctor and patient. Exercises should be carried out for an hour or two at a time, with long pauses for rest, and treatment continued for three or four months. In hemiplegias treatment should not be delayed more than four weeks after the beginning of the attack.

FRANCK presented two women who had suffered from *trigeminal neuralgia*, and whom he had *cured by injections of a watery solution of osmic acid*, 1 to 1.5 per cent. Sometimes a single injection suffices; but if the nerve is not found by the first injection, it is necessary to repeat the attempt. The injection itself is painful, but it is followed by anesthesia in the region of distribution of the nerve. EULENBERG endorsed this treatment, cautioning the members to always have a freshly prepared solution, as solutions of osmic acid decompose easily.

At the session of this Society December 20th, JARISLOWSKI said that the *prophylactic value of periodic sweats*, which is claimed by Ziegelroth, is not yet proved. They have a great value in stimulating and cleansing the skin. For some persons the steam baths are more to be recommended, and for other Russian baths. He cautioned against too long continuance of a steam bath.

BELOW spoke of the use which is made of sweats in the tropics to cure syphilis, by allowing patients to lie in heated river or sea sand. This treatment increases the pigmentation of the skin, as sun baths do. This effect of heat, without sunlight, upon the pigment of the skin ought to be further studied.

Medical Anachronism in Fiction.—Harry Thurston Peck, Professor of Latin at Columbia University, in a review of "Quo Vadis" says: "There is an anachronism involved in the introduction at the end of the ninth chapter of a freedman 'with his face marked with smallpox;' for no mention of smallpox in Europe is found till four hundred years after the period described in 'Quo Vadis,' and no Roman author speaks of such a disease."

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held January 4, 1898.

THE President, B. SACHS, M.D., in the Chair.

RACHITIS; PETIT MAL; ARRHYTHMIA OF THE HEART.

DR. WILLIAM HIRSH presented two boys, brothers, one being six, and the other, three years of age. When each one was a year old a severe epileptic attack occurred, and this was succeeded by frequent attacks of *petit mal*. Almost immediately after the first attack the father noticed something wrong with the eyes. Examination now shows an internal strabismus, apparently due to a paralysis of the right external rectus muscle. Both boys are very markedly rachitic, and in both the heart's action is of that type which the Germans call "gallop rhythm." Both boys present in like degree that scaly condition of the skin, termed ichthyosis. In the eyes of both children there is a condition identical with that described in the adult as "choked disc." Both children exhibit choreiform movements, and both are idiotic. The speaker said that there does not seem to be a single lesion which will explain all these symptoms. There is no history or other evidence of syphilis. A little girl of the family, born between these two children, is well developed, both physically and mentally. The father and mother are cousins.

DR. LANDON CARTER GRAY remarked that attacks of *petit mal* in rachitic and choreic children are by no means uncommon. These cases usually recover under a treatment which improves the general nutrition.

DR. W. H. THOMSON remarked that the rhythm of the heart appeared to be due to hypertrophy of the right ventricle.

DR. HIRSCH replied that these cases are peculiar, because of the existence of choked disc, absence of patellar reflexes, and the peculiar rhythm of the heart.

A CASE OF PROGRESSIVE MUSCULAR ATROPHY.

DR. FREDERICK PETERSON presented a case of this kind. It was that of a girl of eighteen years who, at the age of seven years, had an attack of measles, six months after which she began to drag the right foot, and shortly afterward the left. There is no hereditary taint of any kind in the family, and except the measles she has never had any disease peculiar to childhood. Her drop-foot led to the application of orthopedic treatment for several years, though the weakness and wasting in the legs below the knees grew gradually worse in spite of such treatment. Two years ago she noticed beginning wasting and weakness in the hands. She had never had any pains in the hands, arms, legs, or feet. Examination shows the condition at the present time to be as follows: Pupils and eye muscles are normal. There is slight scoliosis; shoulder and arm muscles well developed and normal; thigh and hip muscles well developed and normal. She presents double *main en griffe* and double talipes varus with drop-foot. There is reaction of degeneration in all the intrinsic muscles of both hands, and in the

muscles of the legs below the knees. There are no sensory changes whatever. The plantar reflexes are present. The knee-jerks are absent. She sways on standing. There is no incoordination of the muscles. Her general health is excellent. She presents, therefore, all the typical features of the peroneal form of progressive muscular atrophy; *viz.*: perfect preservation of the general health, remarkable contrast between the tapering wasted extremities and the well-developed muscles about the extremities where they are attached to the body, protrusion of the internal femoral condyles, garter-like atrophy of the legs below the knee-caps, talipes varus, *main en griffe*, fibrillary tremor, equine gait, and a tramping movement on standing in one one place (like a horse in a stall). There are fewer than sixty cases of this form of progressive muscular atrophy on record, and some of these, at least, are not genuine, but probably poliomyelitis. The seven autopsies recorded show that the lesion is a multiple neuritis, so that this—the Charcot-Marie-Tooth form—is a connecting link between the Duchenne-Aran or spinal type of progressive muscular atropies and the primary muscular dystrophies.

DR. SACHS said he believed he had been first in America to describe this disease. He had first seen it in two brothers, and the cases had been published in *Brain* in 1890. He had proposed at that time to regard the disease as the "leg" type in contradistinction to the "hand" type of progressive muscular atrophy. Only two months ago another case came under his observation. In almost all of the reported cases the extensor muscle of the great-toe was the first part affected. The last autopsy reported, one made by Oppenheim, showed that there is positively no change in any part of the central nervous system, and that it is after all a disease of the muscles—in other words, that it may be as closely allied to the dystrophies as to the spinal diseases.

A CASE OF PROGRESSIVE MUSCULAR DYSTROPHY.

DR. W. H. CASWELL presented a man, twenty-seven years of age, a silk weaver by occupation. His family history is negative. For some years he had had weakness of the arms. There is no history of serious illness or of syphilitic infection. Examination shows a decided hollowing of the thorax in the infraclavicular region, and the shoulders are carried more forward and inward than usual. Some of the muscles about the arm and shoulder are atrophied and others hypertrophied. He can only extend the arms laterally to the horizontal, but another person easily raises them above his head. The right half of the face presents a flatness and weakness. Electric examination shows faradic contraction in all the muscles, though diminished in those which are atrophied. There is no reaction of degeneration anywhere. The case, therefore, is one of progressive muscular dystrophy of the facio-scapulo-humeral type.

DR. L. STIEGLITZ said that he had had this case under observation for some months. He wished to direct attention to the changes around the orbit. The palpebral fissure on the left side is larger than on the right. At times, if the patient looks down, the lid of the left eye will not immediately follow the movement of the eyeball —Gräfe's symptom. In these cases he thought the face was involved very much oftener than Erb originally believed. When the face is involved, it is not usually affected symmetrically—an important point in differentiation.

BLINDNESS FOLLOWING CRYING.

DR. W. B. NOYES presented a little girl of eight years, having a negative family history. Four years ago, after a good deal of crying, the sight began to fail, and in four months she was blind. . The child had had headache, right internal strabismus for a few weeks, and occasional vomiting, but no fever. Examination showed double optic atrophy. With the symptoms just narrated a clinical picture is formed which might have been taken for that of a brain tumor. The vision is reduced to the mere perception of light. The child is in good general health. His own idea is that the child originally had a subacute meningitis, which gradually involved the optic nerves.

DR. W. M. LESZYNSKY said that primary optic atrophy is very rare in children, and he is, therefore, inclined to believe that a localized basilar meningitis had been the primary condition. Some years ago he had presented to the Society a case showing this form of meningitis, although it did not involve the eyes. The cases are not very uncommon, and are liable to follow the exanthemata. At the time of reporting his case, he had referred to the one reported by Hobb of Zurich, in which the diagnosis had been confirmed by autopsy.

DR. MARY PUTNAM JACOBI asked if the presence of tubercle could be entirely excluded.

DR. NOYES replied that he could not bring himself to believe that this child had tuberculosis, but that she had been infected with syphilis is barely possible.

TORTICOLLIS SUCCESSFULLY TREATED WITH CONIUM.

DR. GRAEME H. HAMMOND presented a young man who had developed torticollis during last March, and in whom the spastic condition was still present when he first came under observation during September of last year. The patient was now taking 90 drops of the tincture of conium three times daily, and exhibited none of the toxic symptoms of the drug. No improvement had been observed until the dose had been increased to about 40 minims three times daily.

DR. H. ALLEN STARR said that he had had a case which was very much improved by the same treatment after the dose had been increased to 30 minims three times daily.

DR. W. H. THOMSON said that a very prominent oculist had caused the death of a patient suffering from blepharospasm by giving him 25 drops of the tincture of conium.

DR. GRAY said that more than one fatal case from the use of this drug had been reported; the trouble seemed to be that it was impossible to obtain a stable and reliable product. If, therefore, he happened to secure a good preparation for a given case, he endeavored to continue the use of the particular specimen until the patient recovered.

DR. HAMMOND said that most of the fluid extracts of conium found in drug-stores are almost inert. He always specified "Squibb's, and always began with a dose of 4 drops, and increased the dose by one drop daily. The system soon becomes tolerant of the drug.

AN UNUSUAL CASE OF RECURRENT MULTIPLE NEURITIS OF UNCERTAIN CAUSATION, WITH PARALYSIS OF THE PHRENIC NERVE.

DR. M. ALLEN STARR said that in cases of paralysis from multiple neuritis developing subsequently to the acute infectious diseases, there is rarely any tenderness along the nerves. It is only in the more severe cases that any cranial involvement is observed. Disturbance of respiration, from involvement of the diaphragm, is the rarest of all, and naturally is of the gravest significance.

The patient who forms the subject of the present report first noticed during 1892 a clumsiness of his hands, and shortly afterward he was unable to stand. There had been no preceding sore throat. Within three weeks he was unable to use his hands, walk, or stand alone. Control of the bladder and rectum was normal. During October, 1892, he was seen by Dr. Starr at St. Luke's Hospital, and then had total paralysis of all the muscles below the knees and elbows, with considerable atrophy of these muscles, and loss of faradic excitability. The trunk muscles had not escaped. There was partial wrist- and foot-drop, but no sensory disturbances. After a month he was able to go home, though he could not stand alone. In July he was reported as having fully recovered. In August, 1894, he was readmitted in about the same condition as at first. The second attack began during July of that year, with an almost total paralysis, as before. In September he developed a multiple neuritis. The next month he was able to leave the hospital, and the following April reported that he had regained complete power of all his muscles. On September 20, 1897, he came to Dr. Starr's office complaining of some numbness in the fingers and toes. There was slight anesthesia in the fingers up to the second joints. His appearance was that of a young athlete. In the course of a month there was absolute total paralysis of all the muscles of all the extremities, with rapid atrophy and loss of faradic reaction; he could not sit up, and his speech was noticeably thick. Early in October, while in the hospital, deglutition became affected; then the respiration suddenly became unnatural, and it was found that there was no spontaneous action of the diaphragm. This lasted two weeks, and he could sleep but little during this time because of the necessarily conscious effort at respiration. The diaphragm gradually resumed its functions during the following month and improvement advanced rapidly in all of the muscles. At the present time he is able to walk with the aid of crutches.

This case, Dr. Starr said, presented many of the features of diphtheritic multiple neuritis, yet he had not been able to find any recorded cases of this form of neuritis in which there had been a recurrence. Gowers states that involvement of the pneumogastric a second time in alcoholic neuritis is almost uniformly fatal. The causation of the multiple neuritis in this case could not be easily determined. It is easy to rule out alcoholism. Diphtheria was suspected, but careful questioning failed to elicit any history bearing on this point. Cultures were made from the throat on several occasions, and bacilli were found, similar to the Löffler bacillus, but injections of these cultures into guinea-pigs gave entirely negative results.

DR. SACHS reported a case of recurrent multiple neuritis of syphilitic origin that he had had under observation for a number of years. The patient was a man, thirty-five years of age, temperate in all his habits, who had been married two years. There was a history of a syphilitic infection three years previously, in 1892. During October, 1895, he first noticed difficulty in going up and down stairs, and this was quickly followed by marked paresis of both lower extremities, considerable atrophy of the anterior thigh and also of the tibial muscles. The knee-jerks were entirely absent; there was no evidence of spasticity, and there was good control of bladder and rectum. Under a course of mercurial inunction improvement was immediate, and early in 1896 he was able to go about as well as before the illness began. The patient again consulted him in May, 1897, because of a slight left ptosis. This disappeared after a course of inunctions. In November, 1897, he complained of numbness in the left hand and fingers. Examination showed the power of the hand to be almost nil. There was gradual involvement of the musculo-spiral, median, and ulnar nerves, with loss of faradic response. All these symptoms pointed to the neuritic character of the affection. He had seen only one other case which at all resembled this one.

DR. HIRSCH asked if the spleen had been enlarged in Dr. Starr's case, and whether the blood had been examined for the malarial plasmodium. He recalled one case of multiple neuritis occurring from paludal infection, as demonstrated by the presence of the plasmodium in the blood. He had seen a case at Professor A. Fränkel's clinic, in which there were two attacks of multiple neuritis, finally ending in tabes. He thought a number of cases were on record in which tabes had been preceded by a history of multiple neuritis. This seemed to confirm the theory of Leyden, that tabes originates, not in the posterior columns, but in the ganglia.

DR. STARR replied that malaria had been excluded in his case by examination of the blood, and that the spleen had been of normal size.

DR. HAMMOND said that he now had under treatment a patient whose case is similar to the one reported by Dr. Starr. After having been in the hospital for a few days the patient's symptoms had all been aggravated, following two distinct paroxysms of intermittent fever, except that there was no return of the paralysis of respiration. This man had had chills and fever at intervals for fifteen years previously, and his original attack had occurred shortly after a paroxysm of this disease.

DR. MARY PUTNAM-JACOBI remarked that in the last number of *Brain* Fleming had reported a case of multiple alcoholic neuritis, occurring in an alcoholic subject, in which at the end of three months there had been

involvement of the phrenic nerve, and death had ensued after six hours of most intense dyspnea. The autopsy showed a degeneration of the phrenic nerve, and also hemorrhages into the anterior horns of the spinal cord.

DR. FRAENKEL said that he had under observation two cases similar to the one reported by Dr. Starr. One entered the Montefiore Home about three years ago—a case of poisoning by snuff. He returned twice with a new and more severe attack. The second case was that of a man, forty-four years of age, who had had three attacks of multiple neuritis. Each time the relapse had followed his return to a house the walls of which were covered with green wall-paper, thus establishing a possible source of arsenic poisoning.

DR. SACHS said that he could recall one case of multiple neuritis, exactly like Dr. Starr's, in which intense dyspnea had been a prominent symptom, death occurring with unusual suddenness. In the case that he had just reported, the ptosis was mentioned simply to prove that the entire nervous system was affected by the syphilis; the ptosis might be due to peripheral disease.

BRAIN TUMOR— PRESENTATION OF A PATIENT AND OF A SPECIMEN.

DR. FRAENKEL presented a little boy, seven and one-half years old, in whom there was facial asymmetry—most noticeable when he smiled. The skull was also asymmetric, and there was enlargement of the cervical and inguinal lymph-nodes. There were no knee- or elbow-jerks, and the muscles of the right half of the body were more flabby than those of the other side. During July, 1896, he began to have attacks of vomiting and severe headache, and became dull and drowsy, and a right facial palsy developed. On examination, the right angle of the mouth was found to have dropped, and he had an ataxic-hemiplegic gait. He showed mental hebetude, and his speech was slow and stammering. There was distinct tumefaction of the right optic disc; the right facial nerve appeared paralyzed in all its branches, and the motor power of the right upper extremity was diminished. A diagnosis was made of subcortical brain tumor, probably in or near the optic thalamus. Mercurial inunctions and the internal administration of iodid of potassium soon caused improvement in all the symptoms. After three weeks the subjective and most of the objective symptoms had disappeared.

Dr. Fränkel then presented a brain, removed from a man twenty-nine years of age, who had been admitted to the Montefiore Home on August 20, 1895, suffering from pulmonary tuberculosis. There was a moderate lesion at the apex of each lung. Examination showed edema of the lower extremities, anemia, lesions of both lungs and enlargement of the liver. The skull was asymmetric. The most prominent feature was the facial expression; the left eyelid drooped and the eyeball was injected. The right facial nerve was found to be normal. The patient performed all the motor functions with the left facial nerve, and with unnecessary force. The tongue was dry and furred, and not tremulous. The knee-jerks were very much diminished. There was no ataxia. He was given mercurial inunctions, and iodid of potassium was administered internally. After two weeks he complained of vertigo, and developed a typical cerebellar gait. Treatment was continued three weeks longer, at which time most of the symptoms had disappeared. The diagnosis seemed to lie between meningitis and a tumor at the base of the brain—in the posterior fossa. The patient finally died in uremic coma. The autopsy was made by Dr. William Vissman. No abnormalities of the spinal cord or of the dura mater of the brain were found. At the base of the brain were a number of grayish-white nodules, the exact nature of which had not yet been determined. The anatomic diagnosis was tuberculous meningitis of the base of the brain, pulmonary tuberculosis, and the nervous affection was thought to be entirely functional. Tubercle bacilli were never found in the sputum.

Dr. Fränkel was of the opinion that the first case was specific, and that in the second the lesion was undoubtedly tuberculous. The specimen showed that it had, for the most part, disappeared.

REVIEWS.

LECTURES ON THE MALARIAL FEVERS. By WILLIAM SYDNEY THAYER, M.D., Associate Professor of Medicine in the Johns Hopkins University. New York: D. Appleton & Co., 1897.

So widely known is Dr. Thayer's original work in the study of the malarial fevers that a new contribution on the subject from his pen is quite likely to invite attention and interest. The reader of his lectures will not be disappointed. The subject is presented here with a facility born of actual knowledge, with a scientific instinct that is developed on the first page, and with a literary grace so charming that one is inclined to believe that the author's previous work will be eclipsed by the present.

Beginning with a thorough historic review of the literature of the disease, Dr. Thayer points out the poor choice of name for the malarial parasite, the "plasmodium malariæ," and utters the hope that it may soon be permanently replaced by a title more appropriate. He emphasizes the necessity of knowing well the histology of the normal blood before attempting to study that of disease. He leads us next into the detailed methods of staining and studying malarial blood, and discusses the distribution and transmission of the parasite. It is interesting to note that the author doubts the transmission of the disease from mother to child, and he cites an instructive case in defense of his view. The clinical appearances of malaria, its sequelæ and complications, are next considered, and are followed by a thorough discussion on treatment, a chapter which was, unfortunately, all too short in the monograph of Thayer and Hewetson, but whose excellence in the present work wholly atones for that omission. A chapter on general pathology and one on diagnosis complete the book.

The work of the Johns Hopkins school in setting aside "malaria" as a diagnosis of self-satisfaction will, in the course of time, be appreciated by the profession, and the present work can only tend to enhance this scientific effort.

The book is elegantly made and is illustrated by several temperature charts and by plates modified from the original ones published in 1895.

THERAPEUTICS: ITS PRINCIPLES AND PRACTICE. By H. C. WOOD, M.D., LL.D., Professor of Materia Medica and Therapeutics, and Clinical Professor of Diseases of the Nervous System in the University of Pennsylvania. Tenth edition. Philadelphia: J. B. Lippincott Company, 1897.

THAT Professor Wood's famous work should reach its tenth edition is no surprise to the thousands of physicians and students who have long regarded it as *the* American text-book on the subject of materia medica and therapeutics. It is so well known that any laudation of it will be superfluous.

The present edition has been brought thoroughly abreast of the times, the newer remedies finding such room as they seemingly deserve within its pages. The antitoxins, eucain, Schleich's infiltration anesthesia, for example, are well discussed, and every chapter shows the touch of Dr. Wood's wide reading and extensive learning. The tenth and succeeding editions will find an abundance of readers.

THE AMERICAN TEXT-BOOK OF OPERATIVE DENTISTRY. Edited by EDWARD C. KIRK, D.D.S., Dean of the Dentistry Department, University of Pennsylvania. Philadelphia and New York: Lea Brothers & Co., 1897.

THIS is a system by fifteen authorities on subjects relating to dentistry. Appended is a list of the contributors, with the subjects treated:

R. R. Andrews writes on the embryology and histology of the dental tissues; Henry H. Burchard, on plastic fillings, their properties, uses, and manipulations; including a history of amalgam, its physical properties, giving diagrams and tables of its shrinkage, expansion, etc.; the treatment and filling of root canals; the pathologic conditions which obtain, and the therapeutic agents and materials used in their treatment. Dento-alveolar abcesses, their causes, pathology and morbid anatomy, with diagrams by Dr. Black, together with the latest methods of treatment, are next considered. Local anesthetics and tooth extraction are the succeeding topics discussed.

Calvin S. Case discusses the development of esthetic facial contours, and William E. Christensen writes of inlays, the setting of porcelain cavity stoppers, the process of forming and fusing porcelain inlays by the use of the Downir crown furnace, and the Custer electric furnace. Dwight M. Clapp considers combination fillings. M. H. Cryer writes on the extraction of teeth and surgical anatomy of the maxillæ; the treatment of abnormalities, with instruments and accessories employed.

Edwin T. Darby is the author of the operation of filling cavities with metallic foils and their modifications. Clark L. Goddard discusses care of the deciduous teeth, and the character of the filling materials for the same. S. H. Guilford writes on the preparation of cavities, with descriptions of instruments used.

Louis Jack considers the examination of the teeth preliminary to operation, describing the methods, instruments, and appliances. Wedging and other methods of securing separation of teeth, including the exposure of cervical margins by slow pressure. The preparation of cavities and treatment of hypersensitive dentine by sedatives, obtundents, local and general anesthetics, is next described. Sterilization, with a consideration of the physiologic and therapeutic action of medicaments used, follows.

Edward C. Kirk writes on discolored teeth and methods of bleaching; Louis Ottofy, on plantation of teeth; C. N. Pierce, on pyorrhea alveolaris; J. D. Thomas, on extraction of teeth under nitrous oxid anesthesia. The last chapter is by Alton Howard Thompson, on the microscopic anatomy of the human teeth, with diagrams of the types of the dental arch and occlusions of the teeth.

The work is handsomely and beautifully illustrated, and should be a valuable acquisition to every dental practitioner, being a thorough *résumé* of the subject of operative dentistry, written in a modern spirit by competent authorities.

THERAPEUTIC HINTS.

For Chloasma.—

℞ Hydrarg. bichlor.	. . .	gr. viii
Ammon. chlorid.	. . .	gr. xlviii
Spts. rect. .	. . . .	ʒ vi
Inf. hamamelidis	. . .	℥ iii.

M. Sig. Apply small compresses wet with this solution to pigmented spots.

For the Arrest of Acute Coryza at its onset, the following powder is recommended:

℞ Salol	. . . . .	gr. xv
Ac. salicyl.	. . . . .	gr. iii
Ac. tannici	. . . . .	gr. i
Ac. borici	. . . . .	ʒ i.

M. Sig. Use hourly as a snuff for half a day.

For Gonorrheal Epididymitis.—Apply locally the following ointment:

℞ Guaiacol	. . . . .	ʒ ii
Lanolini, Resorbin } aa	. . . . .	ʒ iii.

M. Ft. ung. Sig. For external use.

A fifty-per-cent. solution of guaiacol in glycerin may be used instead of the above. After the inflammation is subdued it is advised to substitute ichthyol ointment as a resorbent.

For Acne Indurata.—

℞ Plumbi nitrat.	. . . .	gr. xv
Ung. petrolati	. . . .	℥ i.

M. Sig. Apply twice daily.

Administration of Cod-liver Oil.—The following formula is recommended by BRICEMORET:

℞ Ol. morrhuæ	. . . .	℥ vii
Syr. tolutani	. . . .	℥ iiiss
Tinct. tolutanæ	. . . .	gtt. vi
Ol. caryophylli	. . . .	gtt. i.

M. Sig. One tablespoonful two or three times daily. To be well shaken before using.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXII. NEW YORK, SATURDAY, FEBRUARY 19, 1898. NO. 8.

ORIGINAL ARTICLES.

CHOLELITHIASIS, WITH REPORT OF CASES.

BY A. MORGAN CARTLEDGE, M.D.,
OF LOUISVILLE, KY.;
PROFESSOR OF GYNECOLOGY AND ABDOMINAL SURGERY IN THE LOUISVILLE MEDICAL COLLEGE, ETC.

THE importance of this subject seems to be just dawning upon the profession, and it is certain that its history, as written at the close of the next decade, will record one of the most brilliant epochs in surgery. When it is considered that on an average probably one out of every ten persons is at some period of life afflicted with gall-stones, the great frequency of pathologic processes of the biliary ducts, including the gall-bladder, will be appreciated. The old are most prone to have gall-stones, also persons the subject of preexisting disease in this region, such as cancer of the liver and adjacent structures. Women are more frequently affected than men—in the proportion of five to two. Tight-lacing has been considered a cause of cholelithiasis, but sedentary occupation with its attending torpor of secretion and excretion is probably largely responsible for this difference in the frequency of the affection in men and women.

The essential pathology of gall-stone formation consists in an altered condition of the mucous membrane of the bile passages. Once there is destruction of the epithelium, as from extension of inflammatory processes of the duodenum, or from invasion of the ducts by the bacillus coli communis, or from circulatory disturbances resulting from the mechanical pressure of growths, the conditions are at once created for a deposit of cholesterin, carbonate of lime, and bile pigment. The nucleus of such deposits, as well as much of the component mass, often consists of dead epithelial cells and inspissated mucus from the preexisting catarrhal inflammation. The well-known tendency of Americans to so-called gastric and duodenal catarrh, induced by peculiarities of living, such as rapid eating and exertion at a time when large quantities of food are still in the process of digestion, would seem to render them especially liable to this affection.

In detecting the presence of gall-stones too much stress must not be laid upon the presence or absence of jaundice. As a matter of fact most of the patients with gall-stones who apply to physicians for relief have never had jaundice; hence, in the past, they received treatment for something else, the true nature of the disease never being recognized. Severe pain in the right hypochondrium and epigastrium followed by jaundice, which usually passes away in a few days, marks the passage of a gall-stone so plainly that no diagnostic skill is required to surmise the nature of the condition. Or, again, severe sudden pain followed by continuous jaundice usually indicates an impacted calculus in the common bile duct. These are matters of common observation, and need not be dwelt upon in dealing with the symptomatology of the disease. The point in recognizing gall-stones which most deserves consideration is, that such symptoms as have already been enumerated probably do not exist in more than one-tenth the number of cases which come under the observation of the physician. Many patients suffer years with gall-stones in the gall-bladder which are too large to pass the cystic duct; such calculi, of course, never become engaged in the common duct, and so jaundice is not produced. Such cases are most often characterized by attacks of pain, usually requiring several hours or days to attain the greatest severity, with a variable period of persistence, followed by complete relief, the pain subsiding rather suddenly. The explanation of such attacks is to be found in the occlusion of the cystic, or gall-bladder duct, by the stone or stones and the distension of the gall-bladder with mucus. As soon as the passage is cleared by shifting of the stones, the result of the paroxysmal efforts of the muscular gall-bladder, the mucus escapes into the common duct and quiet ensues until the occurrence of another attack.

The pathology of this condition is confined to the gall-bladder and its duct, and from the ease with which the affection may be dealt with, it is especially important to recognize it before the graver complications of common-duct obstruction ensue. During the attacks of cystic-duct obstruction a careful search will usually reveal the enlarged and distended gall-bladder. If we would carefully examine these patients, instead of following the routine practice ot calling the disease an attack of colic or indigestion and giving a dose of morphin, we would often establish a diagnosis of gall-stones in the gall-bladder at a time when operation would give the most brilliant results, and at a time when such treatment may be truthfully said to be preventive of the dangers of gall-stones.

Another and very frequent form of this disease is that in which the stones are very small and very numerous. I have removed more than fourteen hundred distinct but small calculi from a gall-bladder. In such cases one or more stones are passed every day or every few days, and the cystic duct being much smaller than the common duct the little stones usually pass very easily without producing jaundice. However, they give rise to a slight pain and feeling of discomfort, especially in the epigastric region, which lasts from a few minutes to an hour or more. I believe that patients having this form of the affection have been given a large proportion of all the pepsin and other lauded digestive agents which have ever been manufactured.

To recapitulate this part of the subject: (1) We recognize the presence of gall-stones attended with sudden severe pain and jaundice, or by obstruction either temporary or permanant of the common duct; (2) calculi confined to the gall-bladder and cystic duct attended with periodic pain without jaundice and characterized by a tumor composed of the distended gall-bladder in its usual situation (such cystic accumulations vary in size from that of a hen's egg to that of the human head). Occasionally the cystic-duct obstruction fails to be relieved, and the greatly distended gall-bladder may rupture, or, what is most common, become inflamed and adherent to adjacent organs, or to the anterior parieties; (3) cases characterized by slight pain in the epigastrium of varying intensity and duration, but without tumor or jaundice.

In competent hands the surgery of the gall-bladder is to-day the most satisfactory in its results of all abdominal work, and when we reflect how often it could be made preventive of the dread consequences of calculus disease, it should urge us to a due appreciation of the great advantages to be derived from a recognition of gall-stones, if possible before jaundice has become a symptom.

A brief history of fourteen cases subjected to operation is appended. Of these the calculi occupied the gall-bladder, or cystic duct, or both, in thirteen patients. In one case the common duct was alone the seat of obstruction. This was the only fatal case in the series, and in it jaundice had existed during eight months.

Case I.—Mrs. B., aged thirty-six years, the wife of a physician, presented a history of periodic pain of a very severe character in the hypogastric region. Examinations by many physicians failed to determine the cause of her sufferings. There was no jaundice. In the absence of anything more conclusive her trouble was finally diagnosed and treated as gastric neuralgia.

September 19, 1892, I was requested to see her in consultation with her physician and Dr. Scott. The latter, having seen her the previous day, made a diagnosis of over-distended gall-bladder from impaction of stones in the cystic duct. During this last attack, which was most severe, requiring partial chloroform anesthesia for three days, there was a slight degree of jaundice. On examination of the patient I could detect a small tumor, about three inches in length by two inches in width, in the region usually occupied by a distended gall-bladder.

Operation was performed the following day, September 20th. A vertical incision was made at the outer border of the right rectus muscle, extending from the costal arch down to the lowest point of the tumor. The gall-bladder was found very tense and free from adhesions. By aspiration two ounces of clear mucus was withdrawn. The gall-bladder was incised, and several large stones removed, mostly from the cystic duct. The last of these stones was so deeply placed as to impinge upon the common duct, thus causing the slight jaundice from which she suffered. The gall-bladder was stitched to the parietal peritoneum, drained with a rubber tube, and the abdomen closed. Her recovery was afebrile, rapid, and uneventful. Bile flowed freely through the fistula for ten days, after which time its discharge ceased. Her health has been perfect ever since.

Case II.—Mrs. K., aged twenty-five years. Four weeks previously she had been seized with severe pain in the region of the stomach and gall-bladder, which lasted the greater portion of the night, and necessitated morphia, hypodermically, for its relief.

An incision was made as in Case I. The gall-bladder was found to be at least five inches in length and very tense; it was about the shape of a large sausage. The fundus was drawn up into the abdominal wound, a flat sponge placed behind it, and an incision made through which was evacuated about six ounces of clear mucus. Twenty-four calculi, varying in size from that of a small chestnut to a half pea, were removed from the gall-bladder and cystic duct. A drainage-tube was inserted after stitching the gall-bladder to the parietal wound. Bile flowed for about twelve days afterward from the fistula, when the latter closed spontaneously. The patient did not require any opiate, and made a rapid and complete recovery. She has since remained in excellent health.

Case III.—Mrs. S., aged twenty-six years, the wife of a physician, had suffered three years with recurring paroxysms of pain. A small tumor was noticed two years before in the region of the gall-bladder, and it was attended with circumscribed peritonitis. The trouble at this time was thought to be mesenteric tuberculosis. The history was somewhat obscure. There had been marked impairment of the general health, with gradual enlargement of the tumor mentioned. Vomiting was a common symptom. There was no jaundice. The shape of the enlargement was not that of an over-distended gall-bladder, and, moreover, its situation was not typical, being too far to

the right and a little too high up. This enlargement was broadest at the base and not at the fundus. Cystic degeneration of the kidney had been diagnosed. After careful and repeated examination of the patient I believed the trouble to be calculus impaction in the cystic duct. Operation revealed an enlarged gall-bladder with numerous adhesions. The border of the liver was drawn down, very much thinned, and adherent over most of the tumor. The gall-bladder was found to contain three or four ounces of normal secretion. This was drawn off, and five very large calculi found impacted in the duct, causing complete occlusion. These calculi were quite as large as the largest chestnuts. The gall-bladder was stitched in the usual way to the abdominal parietes and drained. The patient made an uninterrupted recovery, and has since experienced the greatest improvement in general health.

CASE IV.[1]—The patient, a physician, aged thirty-two years, had always been very fat, his usual weight being 217 pounds. He presented a history of never having been ill until two years previously. While making a visit to a patient he was seized with severe pain in the region of the gall-bladder, which he at once thought was an attack of biliary colic. This lasted for some time, finally passing off. The subsequent history was that he had numerous attacks of the same kind but of varying severity. During the spring of 1894 he had an attack which was much more severe than usual, since which time he had almost constant pain and was incapacitated for performance of professional duties. Later in the spring he thought he detected an enlargement in the region of the gall-bladder. This became very tender. June 1st he took to his bed. He was under the treatment of his partner in practice. One day he felt, as he described it, something "give way," and he began vomiting large quantities of pus and bile, and actually vomited gall-stones. This was followed by several large bowel evacuations of the same fluid during the course of ten or twelve hours, and in the dejecta were numerous particles of gall-stone débris, together with about one and one-half ounces of sand-like material. His own diagnosis was proven by the operation to have been entirely corrrect, *viz.;* that he had an over-distended gall-bladder, which had become inflamed and adherent to the duodenum into which it had finally broken. After this "giving way," as he called it, he suffered the most intense pain; there was loss of appetite amounting almost to complete anorexia; there was constant pain which confined him to his bed; he became emaciated, falling off in weight to about 160 pounds. In the meantime, he contracted the morphin habit, and, during the late summer months, daily took six or seven grains of this drug when the pain was most severe.

[1] The history of this case is of great importance as showing the probable outcome in the majority, if left to themselves. It also proves that calculus impaction or other impermeable occlusion of the cystic duct must eventually lead to one of two things: Either rupture of the attenuated, over-distended gall-bladder into the peritoneal cavity occurs, followed by inflammation, suppuration, and adhesion to some part of the alimentary canal, or adhesion to the abdominal walls takes place, through which the contents of the gall-bladder are ultimately evacuated.

As I have said, his own diagnosis was absolutely correct, as was demonstrated by the operation, *viz.:* an obstructed gall-bladder containing calculi, adherent and fixed very high up toward the duodenum with which it had a fistulous communication—a natural cholecystenterostomy, but which, on account of the pathologic material still remaining, failed to give relief. Jaundice was present in varying degree from time to time throughout the course of the disease, and evidently corresponded to the passage of some of the calculous débris by way of the common duct. On opening the abdomen the first thing which came into view at the notch of the liver was a thick mass of adherent omentum. I incised this, and gently pushing it out of the way, came down to the under surface of the edge of the liver, but could not locate the gall-bladder. A hard mass was finally detected high up beneath the diaphragm, and after a great deal of trouble I finally isolated the gall-bladder, which was little larger than my thumb and enclosed by numerous adhesions. A further separation of the adhesions brought into view the attachment to the duodenum, it being very high up, probably above the point of entrance of the common duct. The adhesions to the duodenum were very firm. The question was, as I was working high up under the ribs, at least four inches from the point where I would have to make an attachment of the gall-bladder to the parietal peritoneum, whether or not I should carry out my original purpose and establish a fistula through which the débris could be discharged, and allow the communication between the gall-bladder and the duodenum to heal. After great difficulty I succeeded in getting the fundus of the gall-bladder down, and stitched it to the highest part of the wound, which was nearly in the middle line over about what would normally correspond to the situation of the pylorus. I scooped out a large number of small calculi and débris, and placed a drainage-tube in the wound, packing gauze around it, fearing, as there was much tension, that the sutures might give way. The patient rallied nicely from the operation, and on the second day great quantities of this sand-like material were discharged through the drainage-tube. On the third day the whole dressing was for the first time saturated with bile. While the pain continued during the first few days after the operation, yet it was much less marked, and by the sixth day the patient was quite comfortable. The wound healed; his general health is almost perfectly restored, and everything promises a complete recovery.

CASE V.—A woman, aged thirty years, was first seen in consultation. The history was that the patient had suffered more or less continuously with abdominal pain, with paroxysms of greater severity, for about one year. Jaundice was not present. There was some emaciation, and a tumor the size of a fetal head, occupying the gall-bladder region, was detected. A diagnosis of over-distended gall-bladder from obstruction of the cystic duct was reached.

The usual incision being made at the outer border of the right rectus muscle, there was disclosed the largest distended gall-bladder that I have ever seen,

it being quite as large as a child's head. The contents consisted simply of normal mucus. Its enormous weight had drawn it down on a line with the umbilicus. I incised the sac after drawing off part of the fluid, and, passing my finger down into it could at first feel nothing. Passing a finger down to the junction of the cystic and common ducts in the peritoneal cavity, I could feel a large calculus impacted at about the junction of the cystic with the common duct. On again putting my finger into the gall-bladder I could feel the stone, the folds of the duct intervening, but could not bring my finger in contact with it. After drawing up the gall-bladder and putting its walls on the stretch, I was barely able, with the tip of my little finger, to touch a small part of the surface of the stone, but could not move it. With the fingers of the left hand underneath and outside, I could not impart any motion to it. I felt sure there was a constriction on either side of the calculus, and it seemed positive that it was thoroughly impacted or encysted, as I was absolutely unable to move it by my first manipulations. Fully fifteen minutes were consumed in extracting the stone; several times it seemed necessary to incise the duct from the outside and in this way remove the calculus. Finally, however, the distal side of the duct was sufficiently dilated to allow the passage of the stone. The specimen looked much more like a urinary than a biliary calculus. It was very large and of a color that I have never seen before in a gall-stone, being almost white and extremely hard. The gall-bladder was stitched in the usual way, and bile flowed freely through the fistulous opening within eight hours after the operation. This continued for six or eight hours, when it ceased, and has never returned up to the present time, although a small fistula, discharging mucus, has remained. Adhesion of the stricture has probably occurred at the site of the stone, thus cutting off communication between the common duct and the gall-bladder. If the little mucus fistula persists, I shall enlarge the wound and excise the gall-bladder, which in this case can be of no use to the patient.

CASE VI.—A man, aged forty years, five years ago was seized with severe abdominal pain, which was diagnosed by the attending physician as being due to the passage of a gall-stone. Since that time he has had repeated attacks of a similar character, attended with slight jaundice. Within the past year he has not had jaundice, but the paroxysms of pain have been much more frequent than formerly. I saw him November 7, 1894, when he was confined to bed with severe and almost continuous pain in the region of the gall-bladder; temperature, 101° F.; pulse, 100, vomiting and loss of appetite being present. Examination revealed a large tumor below the margin of the ribs on the right side, very broad at its base, and extending as low as the umbilicus. This tumor was quite tender. A diagnosis of overdistended gall-bladder with inflammation was reached.

The usual incision was made. The omentum was found adherent to the fundus of the gall-bladder. The gall-bladder was intensely congested, and presented the evidence of an acute, engrafted upon a chronic, inflammation. Aspiration revealed the presence of pus. After protection with sponges, and having the patient turned upon his side, the gall-bladder was incised and three ounces of pus and twenty-five medium-sized calculi were extracted. There seemed to be complete occlusion of the cystic duct, all stones occupying the cavity of the gall-bladder. After irrigation and drainage of the latter it was sutured in the usual way.

The patient made an easy recovery, bile appearing in the wound on the fifth day. The fistula closed within a few weeks.

CASE VII.—Mrs. W., aged forty-four, married, had suffered a year with periodic pain in the epigastric region, usually lasting less than an hour and recurring almost daily, but with no definite regularity, and independent of any dietary restrictions. In fact, she had been treated during four months by the rest and milk treatment for indigestion. She was very nervous and tired of taking medicine for dyspepsia and gastralgia. February 13, 1896, an exploratory incision was made in the median line above the umbilicus. No abnormality of the stomach was found. The gall-bladder was filled with small calculi. Cholecystostomy was performed. The patient made a prompt recovery, with cure of the gastralgia. The fistula closed within three weeks.

CASE VIII.—Mr. H., policeman, aged thirty-seven years, suffered two years with periodic attacks of biliary colic, slight icterus, great itching of the skin accompanying each attack. Operation was performed April 2, 1896. The gall-bladder was found distended with small calculi (1407). Cholecystostomy; uncomplicated recovery; fistula closed within four weeks.

CASE IX.—Mrs. B., aged thirty-two years, married, enjoyed good health until three years ago. She had had repeated attacks of colic attended with jaundice, and had been treated for congestion of the liver. Eight months prior to the time I saw her she had been seized with a very severe attack of colic, with rapid and profound jaundice, which latter, with emaciation, has continued. Operation was performed, August 22, 1895. The gall-bladder was small, and did not contain calculi, nor were there any in the cystic duct. A single large stone was found embedded in the common duct near the duodenum, around which adhesions were numerous. After freeing the duct it was incised and the calculus removed. The incision was sutured first by fine catgut, and over this a continuous Lembert suture of silk was inserted. It seemed secure. A drain of gauze was carried from the suture-point to the lower angle of the wound. The time occupied in performing the operation was fifty minutes; reaction was very good. On the second day, the patient, a very self-willed woman, arose during the momentary absence of the nurse and crossed the room to where a pitcher of water had been left; she helped herself to this and returned to bed. The following night the dressing showed a bloody discharge of almost tarry consistency. The lower stitches were cut, and a large quantity of dark clotted blood removed from beneath

the parietal peritoneum, but no definite point of bleeding ascertained. Liberal drainage was provided. The bloody oozing continued until death ensued from exhaustion at the end of the fourth day. No autopsy.[1]

CASE X.—Mrs. K., age thirty years, married, presented a history of many attacks of biliary colic during the previous four years. Last attack had been very severe in character. Operation was performed February 7, 1896. Cholecystotomy; removal of twenty-six calculi of various sizes. Easy convalescence; fistula did not close until the end of six months.

CASE XI.—Mrs. H., aged fifty-eight years, presented a history of much pain and soreness in the right hypochondrium during the previous five years. She recently had had some fever, but never jaundice; a large tumor in the region of the gall-bladder was easily detected. At the operation, February 14, 1896, the gall-bladder was found to contain a pint of pus and between sixty and seventy gall-stones. Cholecystotomy; bile discharged through the fistula on the second day; easy recovery; fistula closed five weeks after the operation.

CASE XII.—Mrs. S., aged thirty-three years, married, presented a tumor in region of the gall-bladder as large as a fetal head; little pain; never had had jaundice. Operation was performed May 25, 1896, and the gall-bladder was emptied of a quart of clear mucus and probably four hundred calculi, most of which were impacted in the cystic duct. Bile appeared through the fistula on evening of the first day after the operation; quick recovery; fistula closed within eighteen days.

The following case is, I believe, unique in the history of gall-stone operations:

CASE XIII.—Mrs. R., aged thirty-nine years, presented herself for treatment during April, 1896. She was much emaciated and was confined to her bed most of the time. She suffered great pain and tenderness in the region of the liver. She gave a history of having had pains in this region during several years, but the present illness dated back four months, at which time she had a chill, followed by fever, the latter being more or less continuous ever since. Examination revealed the presence of a large mass continuous with the liver and reaching as low down as the umbilicus. Careful palpation led me to believe that the enlargement was the liver.

Exploration, April 6, 1896. On opening the peritoneum the liver was found to be as low as the umbilicus, the abnormal position being the result of displacement rather than any increase in size. Attached to the inferior border of the right lobe of this organ, across its entire length, was the transverse colon. Beneath the liver was one inextricable mass bound down by omental, colonic, and duodenal adhesions. The mass was undoubtedly inflammatory, and, from the history of the case, I was satisfied that it contained pus. So great were the adhesions to the transverse colon that the liver was drawn down almost from beneath the ribs. The condition impressed me as probably being an abscess of the under surface of the liver. I did not think it wise to attempt a separation of the visceral adhesions which would contaminate the abdominal cavity with pus in a situation which it is impossible to drain satisfactorily. The superior (now anterior) surface of the liver was free and in no way adherent to the parietal peritoneum. I thrust an aspirator-needle through the lower border of the liver to a depth of three inches, and was rewarded by finding pus. The peritoneum was carefully packed with gauze around a space of liver surface two inches in diameter, the center corresponding to the aspiration-point. An incision one inch long was made into the liver, and deepened until the abscess was opened by means of forceps. Six or eight ounces of pus was evacuated, and the cavity of the abscess thoroughly washed through the opening in the liver. The soiled gauze was now removed and replaced by a coronet of fresh gauze, and a large rubber drain carried to the bottom of the abscess cavity. The upper part of the wound was closed by sutures. The patient made an uninterrupted recovery, the temperature falling almost immediately to the normal. The gauze dam was removed on the third day, and the abscess-cavity, which secreted surprisingly little, was irrigated daily.

The seventh day after the operation, after removing the sutures, I concluded to replace the rubber tube with a small strip of gauze, as there seemed so little discharge. In carrying the gauze through the liver into the abscess-cavity my probe came in contact with a hard substance, the click of which was unmistakably that of a calculus. Believing the liver adhesion to the anterior abdominal wall to be firm, I had the patient etherized, enlarged the tract with my finger, and delivered by means of urinary stone-forceps an enormous calculus nearly two inches in its longest diameter. The drainage-tube was replaced; bile appeared through the fistula four days later, the fistula closing on the twenty-third day after the primary operation. The patient made a rapid and complete recovery.[1]

CASE XIV.—Woman, aged forty-seven years, presented a history of many attacks of biliary colic, accompanied with jaundice. There was some tumefaction over the region of the gall-bladder. Operation was performed November 6, 1896. The right kidney was found displaced and adherent to the under-surface of the gall-bladder. Thirty-six stones were removed. Recovery ensued.

[1] I have assisted at two operations upon patients with common-duct obstruction, but without the marked cholemia of long standing which characterized this case, and the same method of suture and gauze drainage had been employed with perfect success. The operations were performed by my associate, Dr. James S. Chenoweth. It is significant that this unfortunate woman should have passed many stones, and lose her life from arrest, and common-duct impaction of the last one in her collection.

[1] This is the only case that I am aware of in which a gall-stone has been removed through the liver. Had I known the true condition at the primary operation it might not have terminated so favorably for my patient. Had this woman lived without operation, I have every reason to believe that the stone would have been discharged into the colon.

COLLES' FRACTURE AND THE ROENTGEN-RAYS [1]

BY CARL BECK, M.D.,
OF NEW YORK;
PROFESSOR OF SURGERY IN THE NEW YORK SCHOOL OF CLINICAL MEDICINE; SURGEON TO ST. MARK'S HOSPITAL, ETC.

COLLES' fracture is the commonest of all fractures, yet in regard to no other is there more difference of opinion as to treatment. Since the Röntgen-rays began their triumphant march from the modest town on the Main throughout the world, our knowledge of fractures and dislocations has been greatly enlarged, and our methods of treatment revolutionized. It may be safely said that treatises on this subject which were written before the Röntgen era have ceased to be regarded as authoritative. Following the new discovery great interest was at once concentrated on the much disputed classic fracture of the lower end of the radius, and it soon became evident that a much greater variety of the different types of this fracture (which represents ten per cent. of all fractures) exists than was ever anticipated before. As far as my own experience is concerned, I must admit that I never saw a case in which the diagnosis made

FIG. 1.

Colles' fracture with slight sideward displacement.

before a skiagram was taken was not more or less modified thereafter, especially when considerable effusion and swelling were present.

Since March, 1896, I have observed forty-four cases of Colles' fracture, all of which were skiagraphed. Most of the skiagrams revealed conditions not thoroughly anticipated when examined by the usual methods. One most surprising feature was that in nineteen of these cases *a distinct transverse fissure above the capitulum ulnæ* existed, without causing any apparent symptoms. In seven cases the styloid process of the ulna was entirely broken off. In some instances besides the typical transverse fracture there was also a vertical fracture of the radius,

FIG. 2.

Fracture of left radius.

which reached into the radiocarpal joint. In fourteen cases there was no displacement in spite of the great extent of the lesion, the periosteum of the dorsal surface apparently having kept the fragments together.

The clearer our knowledge of a pathologic condition is the simpler and easier will be the indications of treatment. Surely there is a different plan to be pursued if there be a total separation of the lower end of the radius or only a fissure with little or no diastasis. It is of great importance to know the direction of the line of fracture and whether it extends into the joint. Another point which must be considered is whether or not there is any impaction. Sometimes there is a decided turning of the fractured end, its upper margin being forced toward the ulna

[1] Read at a meeting of the physicians of the German Poliklinik, October 29, 1897.

while the lateral margin protrudes and the joint-surface is directed upward to the dorsum. It is apparent that in all such cases unless thorough reduction is at once made the function of the wrist will never be restored; and *vice versa*, if the fracture-line extends upward from the volar side and downward to the dorsum, the displacement must occur in

FIG. 3.

Fracture of right radius.

the opposite manner, the principle of reduction, however, remaining the same. If the direction of the fracture-line is oblique it generally extends into the joint—a point which has to be especially considered in the after-treatment. The method of reduction as well as of applying the dressing will also be modified when there is a fracture of the ulna or of its styloid process, or when a bone particle has been chipped off, as shown in Fig. 2. These lesions are often diagnosed with difficulty by ordinary methods, even when the manipulations are skilled, and are seldom recognized by any other means than by the Röntgen rays; but if the nature of the injury can be clearly studied on the photographic plate, the proper line of treatment is easily determined and may always be followed without subjecting the patient to unnecessary or tentative manipulations.

In the treatment of all fractures there are two very simple rules to be observed: (1) Replace a displaced fragment to its normal position, and (2) keep it there. If the skiagram does not show displacement there is, of course, no need of reduction. This explains why the results in certain cases of Colles' fracture are always good, no matter what sort of treatment is employed. In fact, if treated by a quack, whose ignorance leads him to treat the injury as a sprain with an ointment, poultice, or with "faith," often a better result is obtained in such ordinary cases than by the learned medical neophyte, who, after having made a most erudite diagnosis, immobilizes the joint for too long a period in his zeal to keep the fragments together; there will be no deformity, but adhesions will be formed, and the wrist will remain stiff or immobile. In such a case a patient, the motion of whose hand was not prevented by immobilization, would escape serious consequences. In all cases in which displacement is present of course a great amount of care and deliberation is necessary.

The first requirement, accurate reduction, may be carried out with little difficulty. If forced extension and downward pressure by the surgeon's thumb,

FIG. 4.

Colles' fracture with copious callous formation.

while counter-extension is used on the forearm, flexed rectangularly, should fail, anesthesia must be employed. But the more difficult thing is to keep the fragments well adjusted in a proper position. This I have always been able to secure by applying a long adaptable wire splint (Fig. 4) reaching at the flexor side of the arm from the tip of the fingers to the elbow, the splint being applied while forced

traction is made. If the direction of the displacement is upward—*displacement à la fourchette*, a pad of adhesive plaster is attached to the dorsal integument above the fragment. Then a short narrow splint of wood is placed on the dorsal aspect of the arm, reaching from the metacarpo-phalangeal joint to four inches above the wrist, and is kept pressing down by the application of a gauze bandage. If the tendency of the displacement is downward the same procedure is carried out in the opposite manner, the wire splint being applied on the dorsal and the wooden splint and pad on the palmar side of the arm.

If the displacement be sideways, which is generally the case when there is a simultaneous injury of the ulna, the immobilization must be carried out on entirely different lines. The adhesive-plaster pad must then be applied laterally to the fragment, two long, narrow, wooden splints being used at the same time. One of these splints, being a little broader than the diameter of the bone, begins at the metacarpo-phalangeal joint of the thumb and the other at the same joint of the little finger. Both extend up to the elbow, the same as the long wire splint. If there should be any displacement to the opposite direction, the pad must be applied on the ulnar side. No dorsal splint is used in this variety. After the dressing is finished, the skiagram verifies the proper position of the fragments. If there be much swelling, wet applications may be advantageously used by pouring a solution of acetate of lead, for instance, upon the gauze bandage, the wire splint permitting penetration of the fluid.

It is of the greatest importance in such cases that the fragments, after being properly reduced, be kept *in situ*. The extremely strong ligamentum carpi volare never breaks, as Nélaton well demonstrated, and, therefore, it is in the first instance the *bone* which has to be taken care of.

If after the lapse of a week agglutination of the fragments is obtained and no deformity is evident, then the soft tissues must receive consideration. It is only then that short splints are in order. They consist of well-padded pieces of wood, extending from the metacarpo-phalangeal joint up to the middle of the forearm. After another week they extend only to the wrist, thus permitting free motion of the hand. The patient is told to move his fingers, as in playing the piano. After the third week massage treatment is indicated, active as well as passive motion of the joint being employed at the same time.

If all these points are observed, and if their proper execution is certified by the skiagram, surgical clinics will no longer furnish so much testimony of deformities and functional impairment following Colles' fracture. To illustrate some of the points alluded to, the following cases may be of interest:

Case I.—In this case is shown (Fig. 1) a Colles' fracture with slight sideward displacement in a man, twenty years of age, three hours after the injury was sustained. The small splinters of bone, penetrating the soft tissues, are clearly evident. There is also a distinct fracture-line in the ulna.

Case II.—In this instance is shown a fracture of both radii (Figs. 2 and 3) in a lad of seventeen years, five days after the injury had occurred. On the right (Fig. 3) there is considerable sideward displacement toward the ulna, thus representing a counterpart to Case I., in which the sideward displacement was in the opposite direction. In this case there is also a complete fracture of the ulna. On the left side (Fig. 2) may be seen two radial fragments. The larger one is not displaced, its fracture-line running into the joint. The small fragment is entirely severed and touches the inner surface of the ulna, which is broken transversely at its lower end. Four very small bone-splinters, piercing the soft tissues, can also be clearly recognized. Five days after the injury the patient was presented to an audience of about one hundred physicians, none of them being able to recognize an ulnar fracture, which, indeed, was hardly to be suspected, as the patient could not only walk about without a splint, but also did light work at the time, and was able to lift heavy objects from the floor. There was hardly any swelling and no visible deformity.

Case III.—In this is shown (Fig. 4) a Colles' fracture, after two weeks, in a woman forty years of age. There is but slight deformity. On the day of the injury there was considerable displacement, which was corrected by an able surgeon. There is some copious callous formation, which induced the patient to believe that the "fracture was not set properly." The skiagram convinced her that she had been correctly treated.

Nothing may inculpate or exculpate a surgeon more than a good skiagram. In the May issue of the *International Medical Magazine* I published an illustration which showed an enormous amount of callous; it prevented pronation as well as supination so much that the case was pronounced to be one of vicious union. It was only the skiagram that exonerated the attending surgeon.

MIDWIVES.[1]

By HENRY J. GARRIGUES, M.D.,
of New York;
Consulting Obstetric Surgeon to the Maternity Hospital; Visiting Gynecologist to St. Mark's Hospital, etc.

During 1884 a bill was introduced in the State Legislature the aim of which was to grant a charter to a certain college of midwives in this city. After a heated discussion in the County Medical Society a resolution was passed in opposition to the enactment

[1] Read before the Section on Obstetrics and Gynecology of the New York Academy of Medicine, January 27, 1898.

of the bill referred to. Dr. Albert W. Warden and I were sent to Albany as delegates to confer with persons of influence in the matter, and the bill was eventually killed.

So far as I know, nothing has been done since that time to regulate the practice of midwifery in this city, but of late the question has been brought up in the Society of Medical Jurisprudence, and the hope was expressed that adequate legislation might be secured "to regulate the practice of midwifery by midwives in our Empire State."

In this State there are no general laws concerning midwives, and but two that are special, one for Erie County, and the other for the City of Rochester. The one for Erie County, in which is situated the City of Buffalo, was passed on May 22, 1885, and forms Chapter 320 of the laws of the State of New York for that year.

It prescribes that the county judge shall appoint a board of examiners in midwifery, to consist of five members who shall have been licensed to practice physic and surgery in this State. They shall on the first Tuesday of October and April of each year, and on such other days as said board may appoint, examine candidates of the age of twenty-one years or upward, possessed of good moral character, who shall present themselves to be examined for license to practise midwifery in the County of Erie; and shall, on receipt of $10, issue a certificate to any person so examined who shall be found by them to be properly qualified. The money received shall be applied to defray the expenses of the board.

The successful candidates are entitled, within the County of Erie, to practice midwifery in normal labors, and in no others; but such persons shall not in any case of labor use instruments of any kind, nor assist in labor by any artificial, forcible, or mechanical means, nor perform any version, nor attempt to remove adherent placenta, nor administer, prescribe, advise, or employ any poisonous or dangerous drug, herb, or medicine, nor attempt the treatment of disease, except when the attendance of a physician cannot be speedily procured, and in such cases such person shall at once and in the most speedy way procure the attendance of a physician. The board shall have power to recommend to the Judge of Erie County the revocation of a license, and said judge shall have power to revoke the same.

Any person who shall practise midwifery, or without the attendance of a physician when one can be procured, attend a case of labor within the County of Erie, without being duly authorized so to do under existing laws of this State, or without having received and recorded the certificate named above, and any person who shall violate any of the provisions of this act, shall be fined not less than $50 or more than $100, and shall forfeit any certificate theretofore granted under the provisions of this act.

The act regulating the practice of midwifery by others than legally authorized physicians in the City of Rochester forms Chapter 842 of the laws of the State of New York for 1895, and is, with slight modifications, a verbatim copy of the Erie County act. In Syracuse some time ago the local Board of Health passed a resolution compelling all midwives to register with the Clerk of Vital Statistics, but the County Clerk writes me that he does not think the city ordinance has been lived up to.

In regard to our own city, there is no law whatever regulating the practice of midwifery. The only restriction of any sort is contained in Section 5 of the Sanitary Code of the Board of Health, which requires midwives, as well as physicians, to register in the office of the Register. No qualifications whatever are or can be demanded of any person registering in that office as a midwife. Under the law, or absence of law, any person may practise midwifery.

There are at least five schools of midwifery in this city in which instruction is given and diplomas are issued.

This condition of things is certainly astounding in a civilized country at the end of the Nineteenth Century. Still, if the remedy is to be any kind of official recognition of midwives, and the establishment of one or more legally chartered colleges for midwives, or the appointment of examining boards with the right to grant certificates entitling the candidates to practise midwifery, then I prefer the present chaos, for the simple reason that it cannot last forever, and that it must lead to the enactment of a law by which midwifery, as all other branches of medical practice, is exclusively placed in the hands of the medical profession, where it belongs.

The conduct of labor used to be, and among uncivilized people still is, the exclusive domain of women. Originally any woman who had herself borne children assisted her friends during this ordeal, but in the course of time special authorized guilds of midwives were formed who alone possessed the right to practise the art, and who only called in a physician when they found themselves incapable of completing the delivery.

It was in the beginning of the Seventeenth Century that in Paris doctors first began to assume the direction of normal labor cases. As early as the year 1600 Charles Guillemeau and Honoré began to be in great request by most ladies of quality. Louyse Bourgeois deplores, of course, the immodesty and wantonness of the women of her day, which led them to prefer male physicians, even in ordinary labor.[1]

In England physicians were not employed in normal labors before the end of the last century, and

[1] Wm. Goodell: "A Sketch of the Life of Louyse Bourgeois," pp. 40–41. Philadelphia, 1876.

at first the so-called men-midwives met with great opposition. In Germany the old system obtained much longer, and to a great extent still exists, but it has become quite usual for well-to-do women to employ physicians instead of midwives. In Denmark, also, some years ago physicians began to be employed as accoucheurs.

The reason of this gradual domination of the field of midwifery by physicians is that the superiority of the new over the old system at once becomes manifest wherever it is tried.

I do not share the view of Louyse Bourgeois, who, with jealous eyes saw the advent of those dangerous competitors, and pretended it was only the wantonness of the coquettes that made them prefer the assistance of a physician to that of a midwife. Quite the contrary, many modest women have to conquer their natural aversion to the exposure of their person to the sight and touch of a male practitioner of midwifery, but they do so because experience has proved beyond contradiction the superiority of the physician over the midwife.

Of the thousands of midwives who have practised their art only four have given expression to their experience in printed books, three in France and one in Germany:

The oldest work is that of the above-mentioned Louyse Bourgeois (1609), but that of Charles Guillemeau bears the same date. Justine Siegemundin published her "Königliche und Churbrandenburgsche Wehemutter" in 1690. Mme. Boivin dedicated her work in 1811 to Mme. Lachapelle, whose pupil she styles herself. In 1821 the latter published the first volume of her treatise on "The Art of Accouchement," the last two volumes of which were edited by her nephew, Antoine Dugès, Professor of Obstetrics at Montpellier.

Great as the experience and dexterity of these women may have been, the science and art of obstetrics is not a structure of their rearing, but of physicians, from Hippocrates down to the present time.

Obstetric work presents certain peculiarities which make it preeminently objectionable to tolerate its performance by half-taught or entirely ignorant persons. While in other branches of the healing art every case concerns the well-being or restoration to health of one human being, in obstetrics every case involves the fate of at least two individuals. Beside the specific services rendered by the obstetrician, at least three other specialties—internal medicine, surgery, and pediatrics — are more or less constantly involved. In no other department does prevention of evil play a similar rôle. For instance, a cross-presentation recognized before rupture of the membranes may be easily corrected by external version, and thus the necessity for difficult and dangerous operations at a later stage be averted. Very often the demand for immediate action is imperative, so that no time is left for examining books or consulting men of larger experience.

In no branch of the medical art has the inauguration of antiseptic measures wrought greater reduction in mortality. The records of the New York Maternity Hospital, from 1875 to 1883, show an average maternal mortality of 4.17 per cent., in some years running up to between six and seven per cent. During the last six months of this period it was eight per cent., and during the last month of the era referred to, even twenty per cent. After I had introduced strict antisepsis in that institution, the total mortality from 1884 to 1896 sank to 0.83 per cent., or less than one-fifth of what it formerly was.

So essential is antiseptic practice in obstetrics that, without much exaggeration, we may say that the term aseptic midwifery is synonymous with good midwifery, and likewise, septic midwifery with bad midwifery, no amount of personal skill being able in this department to counterbalance the risks connected with neglect of antiseptic precautions. In an apparently simple case the gravest operation may become necessary, and the choice of methods and results depend, first of all, on the aseptic condition of the genital tract.

In private practice the mortality is twice as large as in maternity hospitals, and, although we unfortunately cannot entirely exempt physicians from blame, this sad result is largely due to the employment of midwives. Even in European countries, with their strong governmental supervision, constant complaints are being uttered in regard to the inefficiency and short-comings of midwives. The average midwife is entirely incapable of foreseeing complications; and preach to her as much as you like, she will never grasp, still less carry out, the principles of antisepsis.

To take, as an example, one of the most common occurrences, a laceration of the perineum; if it is not of unusual dimensions the midwife may not be able to see it at all; or, if she observes the injury, she does not realize its importance, and it is to her advantage to conceal it. Thus, the patient is exposed to an infection which may cost her her life, or she may leave her bed possessing the germ of tedious gynecologic disease, while the honest physician will take proper measures to repair the injury, so that the woman regains her health and strength.

Children suffer still more from bad midwifery than their mothers. While still-births in Berlin occur in three per cent. of confinements, they reach nearly eight per cent. in New York. In New Jersey blind-

ness due to ophthalmia neonatorum has increased five times more rapidly than the population.

Midwives not only do harm through their lack of obstetric knowledge, but they are most inveterate quacks. They treat, first of all, disturbances during the puerpery, later gynecologic diseases, then diseases of children, and are finally consulted in regard to almost everything. They never acknowledge their ignorance, and are always willing to give some advice. They administer potent drugs, such as ergot and opium. Their scarcely veiled advertisements in the newspapers show them to be willing abortionists; and since they have the right to give certificates of still-birth, who knows whether or not an infant's death is a natural one?

Although an evil, midwives are, however, in most countries a necessity, in view of the fact that physicians would be unable to find time to do the work. Not so here, where there is a superabundance of medical men. According to the last census the population of the United States on June 1, 1890, was 62,979,766; or, leaving out Alaska and the Indian Territory, 62,622,250. Of these 30,554,370 were females, only 15,742,636 of whom were of a child-bearing age (between fifteen and forty-nine years of age). At the same time there were 104,805 physicians and surgeons, which gives one physician for every 150 women of a child-bearing age; but women do not bear children every year; quite the contrary. We may estimate, even by a liberal calculation, that in America they, on an average, only give birth to four children in all; consequently, the number of women in the child-bearing period (thirty years) must be divided by about eight in order to find the average number of births *per annum*, which gives about nineteen confinements every year for each physician in the United States.

In the State of New York the total population was 5,997,853, of which 3,020,960 were females. Taking the proportion for the United States, this leaves 1,555,190 women of child-bearing age. Now, there were 11,139 physicians and surgeons, or 1 physician for every 139 women of child-bearing age, or an average of 17 births per annum in the State of New York.

In this city, that is the old New York as it existed when the last census was taken, the number of births becomes proportionally smaller. The total population was 1,515,301. Of these 767,722 were females, and by computation it is found that of these 395,556 were of a child-bearing age. As to physicians, the number of male physicians was 3206; that of the females is not specified, but the "Medical Directory" for 1897 shows that in that year there were 145, which gives a total of 3351 physicians and surgeons. Consequently there was one physician for every 118 women in the child-bearing age, or an average of but fifteen confinements yearly for each physician practising in the City of New York. Nobody will contend that physicians cannot easily attend to this number of confinements.[1]

Analogies cannot be drawn from European countries. New York has proportionally to the population nearly twice as many physicians as London, and the United States nearly three times as many as Great Britain. On the continent of Europe there are still fewer doctors, varying from about 1 in 2000 to 1 in 6,000 of the population.

Even the prejudice of those who object to the male accoucheur, can to a great extent be conciliated, as nowhere is there such a number of female physicians and nowhere better trained nurses than in this country. According to the above statistics there were in the United States 4557, in the State of New York, 693, and in the City of New York, 145 female physicians.

Another objection to the exclusive employment of physicians in confinements has been raised on financial grounds. Midwives, as a rule, charge a small fee, and some physicians a very large one for obstetric work, but with the great number of idle physicians, a woman can obtain the services of many a reputable practitioner during her confinement for the same price she pays to the midwife. And if she is too poor to pay even that modest sum, she can, at least in this city, with the greatest facility obtain gratuitous aid, either in a hospital or in her own home, as she may prefer. Of all medical charities none is so overdone as this. I am myself at the head of a department in a dispensary which sends an experienced accoucheur to the patient's home, and furnishes gratuitously all necessary materials, drugs, and medicines, and still only an insignificant number of women avail themselves of this privilege—freely advertised by means of a placard conspicuously placed in the dispensary referred to. What better proof can be offered that this form of charity is already much overdone?

Even in the country the physicians are able to attend to *all* labor cases, and, even if a woman cannot secure medical aid during her confinement, she is much better off when left alone or assisted by a friend than when provided with the services of a midwife.

Under these circumstances there might occasionally occur a tear of the perineum or a post-partum hemorrhage which might have been avoided by timely obstetric aid, but this danger is so small com-

[1] The State of Nebraska has set a good example by restricting all obstetric practice to those who have the degree, Doctor of Medicine.

pared with that of infection that it may be left out of consideration.

The institution of midwives is a remnant of barbaric times, a blot on our civilization, which ought to be wiped out as soon as possible. Since they have never been recognized by the State, except in a few minor instances, the attainment of such an object ought not to be difficult; but since they have been tolerated it would be necessary for the Legislature to enact a law declaring that only licensed physicians shall have the right to practise obstetrics.

The Legislature would not be justified in an endeavor to prevent one woman from assisting another in childbirth, any more than it would be in an effort to prevent one from advising the other to take a foot-bath, or to put a mustard plaster on her chest; but it certainly has the right to prevent a person from exposing a sign as a midwife and practising midwifery for a consideration. It would probably be necessary to respect the so called "vested rights" of those who at the time of the passage of the new law had been, by legal authority, engaged in the practice of midwifery.

It would be eminently proper for the Section of Gynecology and Obstetrics of this Academy to declare itself in favor of a bill restricting obstetric practice, after a certain date, to legally authorized practitioners of medicine; and it would be desirable to have such a bill indorsed by the Academy of Medicine, and by other societies.

If such a law cannot at present be obtained, it is better to leave the question of midwives as it is. Any law embodying a recognition of midwives and the establishment of colleges for their instruction would not only be injurious to the lawful and rational rights of the medical profession, but would result in great danger to the community at large. It would lead to a considerable increase in the number of midwives, while there would be unsurmountable difficulties in the way of legal supervision of them. If a demand for a law, such as the one I propose, be not acceded to by the legislators, the time is not far, when, nevertheless, it will surely be enacted, and any recognition or organization of midwives will only retard this happy hour, when our hopes in this matter will be realized.

As America has led the world in establishing colleges for the education of women physicians, let it also form the vanguard in a war of extermination against the pestiferous remnant of pre-antiseptic days, midwives, and schools of midwifery.

In accordance with the principle herein laid down I offer the following resolution, which I hope may receive favorable consideration from the Academy:

RESOLUTION.[1]

WHEREAS, midwifery, or obstetrics, is an important branch of medical science and art;

WHEREAS, midwives are not recognized by the State;

WHEREAS, Section 153 of the Laws of New York, 1893, Chapter 661, amended in 1895, prescribes penalties for any person who, without being then lawfully authorized to practise medicine within this State and so registered according to law . . . shall assume or advertise any title which shall show, or tend to show, that the person assuming or advertising the same is a practitioner of any of the branches of medicine;

WHEREAS, midwives by their ignorance and lack of cleanliness do great harm to parturient and lying-in women, and assume to administer potent drugs to them without the advice of a physician, and often treat sick women and children, and frequently are guilty of causing abortions.

Resolved, That the Section on Obstetrics and Gynecology strongly recommends the taking of immediate steps to secure the passage of a law providing for the supervision of all persons, not legally qualified physicians, now engaged in practising midwifery, and debarring from such practice all persons not proven to be competent and qualified; and also containing such provisions as, without conflicting with existing rights, shall tend to confine the practice of midwifery to qualified medical practitioners.

CLINICAL MEMORANDA.

A CASE OF FEVER WITH INTERCURRENT PLEUROPNEUMONIA.[2]

BY PALMER C. COLE, M.D.,
OF NEW YORK.

DURING June of last year I was called to see H. G., male, aged thirty-two years. I reached his bedside at 12.30 A.M., and found him delirious and in a high fever; temperature, 104.5 F.; pulse, 120. There was constant vomiting, and his conjunctiva was a deep yellow. Up to a few hours before he had been in apparent good health, coming home in the evening at 9 P.M. after a hard day's work, eating a hearty supper, and about 10 P.M. he commenced to feel ill. At 11 P.M. he had a chill, and took 10 grains of quinin, a hypodermic injection of about 1½ grains of morphin, and went to bed. Vomiting and delirium followed, in which condition I found him.

Subsequent investigation disclosed the fact that he was addicted to the use of morphin, taking about a grain hypodermically every twenty-four hours, as he afterward stated. Judging from symptoms, I concluded that the case was one of acute bilious fever complicated with malaria. I prescribed calomel, soda, and sugar of milk (10 grains of each), to be followed by a seidlitz powder within a few hours if the bowels did not move. The cal-

[1] Passed by the Section on Obstetrics and Gynecology of the New York Academy of Medicine, January 27, 1898.

[2] Read at a meeting of the Northwestern Medical and Surgical Society of New York, December 15, 1897.

omel and soda checked the vomiting, and the seidlitz powder was followed by five copious bilious evacuations. I now gave full doses of quinin, but observing no benefit from the administration of this drug, the dose was reduced the next day to 2 grains three times daily. I also slightly reduced his allowance of morphin, and, as the heart was weak, ordered strychnia sulph. gr. 1/60, and tr. digitalis, 1 minim, three times daily, to be taken alternately every four hours.

There was no improvement, and as I considered his condition critical Dr. Janeway was asked to see him in consultation. He was out of town, and the family called another physician who saw the patient without my knowledge, and who left me written advice to administer 10 grains of phenacetin every four hours, and also wrote that he would meet me the next day. The phenacetin was tried, with injurious results, causing emesis and loss of appetite. It was discontinued after the third dose and previous treatment resumed. The physician referred to was two hours and a half late in keeping his appointment, and in consequence I never met him.

On the morning of the fifth day incipient pneumonia of the left lung was detected. With this complication in a case in which the illness was already critical and the condition steadily growing more grave (pulse, 140; temperature, 104.6° F., respiration rapid, and a weak heart in spite of tonics and stimulants), I made up my mind there was but one hope, which lay in the application of the cold pack.

Having come to this conclusion, I sent for Dr. Simon Baruch.[1] Dr. Baruch was unable to meet me before 10 P.M., when examination showed that there was slight pleuritic effusion on the left side. Dr. Baruch advised the administration of 10 grains of calomel, which was at once given, and then the application of cold compresses was commenced under Dr. Baruch's personal supervision. The temperature of the water used was 65° F., and the compresses were renewed every hour. The cold pack in this case consisted of two heavy linen towels (without fringe, which is important) loosely stitched together and covered with white flannel. On removal the linen was thrown into a large tub of water kept at a temperature of 65° F., and the flannel was dried. The compresses extended from the neck to just below the base of the lungs.

In renewing compresses it is important that the patient *be not* raised in bed, but gently rolled over, a fresh compress taking the place of the one removed, and the patient gently rolled back. In addition to the application of the pack, the patient was sponged with cold water once or twice a day. Dr. Baruch met me the next morning, and, finding no improvement in the symptoms and no diminution of temperature, suggested the advisability of changing the packs every forty-five minutes. Though this was done, there was no improvement, but by evening the right lung was also invaded—without any increase of the affected area in the left, in which the condition seemed to remain stationary. The next morning, as the temperature and pulse were slowly climbing up, I ordered the cold compresses to be applied every half hour, but after about eight hours concluded such frequent changes were not beneficial, and returned to applications every forty-five minutes. This was continued for about eight days, by which time the temperature had fallen to 101° F.; respiration and heart-action decidedly improved, and then the cold compresses were stopped. Convalesence from this time on was slow but uneventful.

Morphin had been entirely withdrawn by the end of the second week, strychnin and digitalis taking its place, and when the patient finally resumed his work he was a well man. He had no recollection of what had occurred during a period of four weeks. He subsequently thanked me more for having cured him of his opium habit than for saving his life. I have not the slightest doubt that the patient owed his life to the persistent external use of cold water, and that under any other treatment he would have died.

[1] Twenty-five years ago I used cold sheets in typhoid fever, but had it not been for Dr. Baruch's invaluable papers and discussions on hydrotherapy, I should not have thought of applying this treatment in pneumonia.

RETROPHARYNGEAL ABSCESS ULCERATING INTO THE LEFT INTERNAL CAROTID ARTERY (?) FOLLOWED BY RIGHT-SIDED HEMIPLEGIA WITH APHASIA AND RECOVERY.

BY MELVIN M. FRANKLIN, M.D.,
OF NEW YORK;
SURGEON TO CHARITY HOSPITAL, AND TO THE OUT-PATIENT DEPARTMENT OF ST. JOSEPH'S HOSPITAL.

THIS case is reported because of its rather unique complications, the happy subsidence of ominous symptoms, and because of the extreme rarity with which such an affection is followed by restoration of health.

A. S., aged seven years, was first seen May 11, 1896. Upon examination it was found that the patient was suffering from a simple angina with very little tendency to any of the subjective symptoms of the affection; there was, however, a slight edema of the posterior wall of the pharynx. A gargle was prescribed, and it was ordered that the child be kept quiet. The next day I was hurriedly summoned, and found the patient in a state of collapse, with blood flowing from the nose and mouth. The child was stimulated with strychnia and atropin and the fluid extract of ergot was injected subcutaneously. Closer examination revealed a pulsating swelling on the left side of the neck. Ice and pressure were applied, and, as a coagulum had formed in the nose and the hemorrhage from the mouth had largely ceased (which might probably be explained by syncope), instead of looking immediately for the cause of the hemorrhage a pint of saline infusion was administered subcutaneously. After this the child's head was gently raised and the mouth opened, when blood was seen gushing from a point posterior to the left tonsillar pillar. With the view of applying pressure internally a soft catheter was introduced through the anterior, and brought out of the posterior nares, and a large piece of sponge was pulled tightly into the vault of the pharynx. The stimulants previously given now began to have some effect, and were continued at proper inter-

vals, so that in the course of a couple of hours the child was in a fairly good condition. At four o'clock the same afternoon the patient was again visited, and the general condition found about the same, but aphasia, together with paralysis of the right side of the face and the right arm, was becoming marked. The paralysis rapidly developed until by six o'clock there was complete loss of sensibility and paralysis of the entire right side of the body, and also complete aphasia. The following morning the condition was much the same, with the exception of an increase in the pulse and a temperature of 101° F. For three days the general condition remained stationary, though the tumor in the side of the neck gradually disappeared. At the end of this time the nasal plugs were removed, after which there was some slight hemorrhage, but this was readily controlled by the use of local hemostatics. In the course of a month the child was able to be about, but could not walk unaided. Several months elapsed, however, before articulation was properly performed. At the present time (a year later) the patient has completely recovered the power of speech and suffers only from a slight disability in the use of the right arm and a talipes equinovarus, the latter being relieved by the use of proper apparatus.

As to the question from which artery the hemorrhage occurred, it is only necessary to glance at the subsequent symptoms to confirm the diagnosis of ulceration into the left internal carotid artery; for, explained in any other way, the case becomes a most remarkable pathologic coincidence. There is already in literature the report of a similar case which, unfortunately, terminated fatally. That the hemorrhage, in my case, should cease spotaneously seems highly improbable, although the nervous phenomena which followed point directly toward the establishment of the diagnosis named. It may be said that other causes than the one already suggested could have produced the hemiplegia, but why should two such unique morbid changes occur practically simultaneously, each bearing directly on the other, and yet so widely different in character? The condition might, again, have been caused by the marked ischemia resulting from the hemorrhage. Whether or not the paralysis was embolic in nature or due to cortical hemorrhage or thrombus, the chief causes of cerebral paralysis, it is difficult to determine, but without a previous constitutional diathesis it is most likely, in a child, to have been caused by an embolus of the middle cerebral artery—a terminal branch of the internal carotid.

SPECIAL ARTICLE.

THE LAPORTE CASE DUPLICATED IN WEST VIRGINIA.

By T. A. HARRIS, M.D.,
OF PARKERSBURG, W. VA.

On the 16th day of January, 1895, Dr. A. S. Keever of Belleville, accompanied by Dr. W. S. Keever of Parkersburg, called upon me at my house. Dr. A. S. Keever asked me to go down to the lower end of the County to operate upon a Mrs. Tice for ovarian tumor. The plan was to go to Belleville the next morning, from which point we were to go to Mr. Tice's house, eight miles from Belleville. Mrs. Tice was a patient of a Dr. Deem (of Tyner, Wood County, W. Va.). Dr. A. S. Keever stated to me at this time that he had seen Mrs. Tice the previous day (the 15th) in consultation with Dr. Deem, and that she had an ovarian tumor which Dr. Deem had previously tapped twice, but failed to empty the sac, as the fluid was too thick to run through the cannula. The little fluid that came away was of a dark, grumous character, and the small quantity removed did not make any impression upon the size of the woman's abdomen. He stated that there was no probability that pregnancy could be a complication, for, while he had made but little examination to determine this point, Dr. Deem had said that he had made a thorough examination and had repeatedly passed a sound into the uterus. They had agreed that she was suffering from blood poisoning and could live but a short time unless an operation was performed for the removal of the tumor.

I objected to going to the woman's house to operate, and stated that I thought the operation would be much more likely to succeed if the woman were first removed to Parkersburg, or even to Belleville. He said it was impossible to move her in her present condition, and he thought I would realize this when I saw her. He stated that it was a condition of emergency, and that if something was not at once done for her she would die, and that soon. I objected to doing the operation in this way, as I had but little expectation of its success, but as a matter of humanity I agreed that Dr. William Keever and I would go down the next morning and do the best we could for her. On the 17th, Dr. Keever and myself went down to Belleville, where we were joined by Dr. A. S. Keever: we rode eight miles up hill and down, over frozen roads and snow, to Mr. Tice's house. We found a small house with one fair-sized living-room, and one or two small rooms adjoining. In the living-room we found Mrs. Tice sitting in a chair; in the room was a bed and a stove. We expected to have met Dr. Deem there, but he had not yet arrived. I sat down by Mrs. Tice (the family were all strangers to me), made some superficial examination, and talked to her about her condition. She told me that the dropsy had been coming on during five or six months; that she had had a lump in her left side. She said that she was not able to lie down to sleep, but had sat in her chair during the last six weeks. The pulse was weak and frequent; temperature about 103° F. She had had chills; the skin was cool and moist; she presented the appearance and symptoms of one suffering not only from the presence of an abdominal tumor, which interfered with respiration, heart's action, and the functions of stomach and bowels, but also of a person suffering from toxemia, the source of which I took to be the tumor which had been tapped, but not emptied, and which was then, and had been for some time, leaking into the abdominal cavity from the hole made in it by the trocar. I told her that I thought we could relieve her of her trouble, but at the same time I explained to her the dangers and uncertainty of the operation which she would have to undergo. She said she wanted to be relieved of her present distressing condition,

for she said she could not live as she was. She was willing and desirous that the operation be performed.

Dr. Deem not having arrived, we concluded to make all the necessary arrangements for the operation. By the time they could be completed we expected he would be on hand, as a messenger had been sent to his house, only a short distance away. We procured a table, and arranged it; the necessary vessels were provided, containing the antiseptics for the instruments and for the cleansing of the hands, etc.; also, towels soaked in antiseptic solutions. Mrs. Tice was placed upon the table for the purpose of a careful examination, and this without any anesthetic; the fact that an ovarian cyst filled the entire abdominal cavity was easily established; there was the mark of the trocar between the pubis and the umbilicus. The breasts were rather large and flabby, the areolæ being darkened in color and having numerous papillæ. Upon passing a finger into the vagina the os uteri was found sufficiently open to admit two fingers, and it projected between the labia so as to be plainly seen without the aid of either speculum or tenaculum. Presenting from within the uterus, just within the dilated os was the head of a dead fetus. At this time Dr. Deem arrived, and he was told of the condition of affairs, and was asked to make an examination, which he did. Then assisted by Dr. Wm. Keever, I proceeded to extract the dead fetus. The mouth of the womb was just within the external genitals, forced down by the pressure of the tumor above, and the efforts of Nature to expel the dead fetus.

In removing the fetus I introduced my fingers into the uterus, after making digital dilation, and with a small pair of forceps caught one foot and brought it down and out. In doing this the body was rotated within the uterus. Making some traction on this leg it came away at the hip-joint. The second leg came off in the same way. An arm, when drawn upon, parted at the elbow. It was plainly evident that the fetus was in a state of decomposition. Securing the pelvis of the fetus with a tenaculum, it was extracted, and the head retained within the uterus. I felt sure that with very slight traction the neck would part, and the head be left loose within the womb. I tried first the tenaculum, but this tore through the skull as it would through a piece of wet paper. I then asked for a blunt hook. Dr. A. S. Keever handed me a piece of ordinary wire slightly hooked at one end, which had been polished with a file and washed in an antiseptic solution. Guiding this wire with my finger, I thrust it into the skull which was just within the mouth of the womb, and extracted the head, the brain oozing out of the opening made by the tenaculum. The entire decomposing fetus had been extracted piecemeal. The cord was limp and flaccid, resembling a piece of tape; it easily parted from the fetus. The placenta was still adherent to the uterus, and was retained. No special effort was made to remove it for fear of hemorrhage from the flaccid uterus. I felt sure that coincident with the occurrence of uterine contractions the placenta would be expelled in the natural way, and also that I could not remove it at this time without the employment of more force than I felt was justifiable under the circumstances. During these procedures the woman laid upon the table without any anesthetic. She made little or no complaint of pain, and then only when I was dilating the mouth of the womb with my fingers.

Having cleansed everything connected with this part of the operation, we made a careful examination and found the woman in as good condition for the removal of the tumor as she was before the extraction of the dead fetus. As said before, up to this time, anesthesia had not been induced, as very little pain was complained of during the previous manipulations; the patient had not lost two ounces of blood, and was in full possession of all her faculties. It was decided to proceed with the operation for the removal of the ovarian tumor. Dr. A. S. Keever administered the anesthetic, while Dr. Wm. Keever prepared the surface of the body for operation, which he did with all antiseptic precautions, scrubbing the surface thoroughly with soap and water, shaving it with a razor, and then scrubbing it again with a solution of bichlorid of mercury, and finally applying towels wrung out in a solution of bichlorid. Everything now being ready, Dr. Wm. Keever and myself prepared ourselves by most thoroughly disinfecting our hands and arms. I took my place on one side of the table, Dr. Wm. Keever, as assistant, being on the other side, with Dr. Deem behind him to act in the capacity of general utility. Before the operation was begun Dr. Deem passed the catheter and drew off the urine.

Upon inspection of the abdomen it presented the appearance of a woman at about the eighth month of pregnancy. At a point about midway between the pubis and the umbilicus was seen the site of the puncture where tapping had been performed by Dr. Deem; the skin puncture had entirely healed. Making, then, an incision about five inches long between the navel and the pubis, the tense skin retracted and the tumor was disclosed, bearing upon its anterior surface the open puncture of the trocar from which the cyst contents were slowly oozing. As there was already an opening in the tumor I did not think it necessary to try to empty it with a trocar at this stage; the opening in the abdominal wall was not long enough to allow so large a tumor to pass through it. The patient was brought near the edge of the table, and I seized the tumor with a pair of forceps at the point of puncture so as to close the opening. She was turned over on her side, nearly on her face, on the edge of the table. The tumor was then punctured with a bistoury, and its contents poured out into a bucket held by her father, assisted by Dr. Deem.

The cyst was multiocular and contained several smaller cysts within the large outer sac; these were successively punctured and emptied. When the tumor had been sufficiently emptied to allow it to be drawn out through the abdominal incision it was found to have no adhesion except a small pedicle connecting it with the left ovary. This pedicle was securely tied with a heavy silk ligature, and dropped back into the abdominal cavity. There being no adhesions, there was no weeping into the cavity. In the pelvis there was a small amount of what appeared to be leakage from the tumor, not more than a spoonful

or two, which was carefully sponged out. The abdominal wound was sutured, dressed, and secured by a bandage, no drainage being provided. The woman was placed in bed, hot applications made to her body, and she gradually recovered from the influence of the anesthetic.

We remained in the house in all two or three hours. Before leaving I had quite a talk with the patient. She had entirely regained consciousness, and was not nauseated. She wanted to know if the tumor had been removed, how large it was, and asked various questions relating to herself. Her pulse and general condition were fairly good under the circumstances; temperature elevated, and skin warm. She expressed herself as being comfortable, and said it was a great relief to be able to lie down, and also that she "had some place to breathe now," respiration being much embarrassed previous to the operation. I parted with her expressing my hope and expectation that she would soon be well. She was left in charge of Drs. A. S. Keever and Deem. She was seen by them the next day, at which time, the placenta having become detached, it was removed and the uterus washed out with a disinfecting solution. She was at that time much in the same condition as before the operation; slightly weaker, and at times slightly delirious. Their prognosis was grave. She died before they met to see her the following day.

The case presents several points of unusual interest, the principal one being the unfavorable condition of the patient previous to operation; she was suffering from the well-marked symptoms of sepsis of such degree as would indicate an early fatal termination. She had been tapped for an ovarian cyst, which had not been emptied of its thick, dark, grumous contents, but was leaking into the abdominal cavity; whence, after undergoing decomposition, this material was absorbed into the general system, producing the blood-poisoning. She was at the same time carrying in her womb a dead and decomposing fetus of about four months. All the complications made a very unfavorable prognosis in an operation performed in a remote country house with few of the necessary comforts, and where she must be left to the nursing of well-meaning but ignorant relatives. It emphasizes the oft repeated advice, "Never tap an ovarian cyst unless you are prepared to operate for its removal." The presence of a dead fetus or a decomposing fetus is not often a complication of this operation. A notable thing, also, is the fact that the continual oozing of the fluid from a puncture of an unemptied cyst will prevent the adhesion of the cyst to the abdominal wall at the point of puncture.

But there is a point connected with this case of far greater interest to the medical profession in the State of West Virginia than anything furnished by its medical aspect. This case has been made the basis of a suit for malpractice against Drs. T. A. Harris, W. S. Keever, and A. S. Keever, and the damages laid at $10,000. The charge stripped of its verbiage is as follows: (1)That the fetus removed was alive; (2) that the mouth of the womb was cut open with a knife; (3) that the fetus was pulled out piecemeal and killed with a piece of rusty, unclean wire, which had been a piece of fencing wire; (4) that the placenta should have been removed at once; (5) that the operation for the removal of the ovarian tumor should not have been done at once, but some (an indefinite) time should have been allowed to elapse between the two (alleged capital) operations; (6) that in emptying the ovarian tumor of its contents a trocar should have been used, and it should not have been punctured with a knife; (7) that in puncturing it with a knife its contents were allowed to flow into the abdominal cavity; (8) that the abdominal cavity was not washed out with any chemic antiseptic.

These several charges were solemnly sworn to either by Dr. Deem or by Mr. Scott (the father of the woman) or by a Mrs. Canary (a relation of Mr. Scott's). When it was proposed to put on the witness stand the doctors concerned in the operation it was objected to by the prosecution, and an article was found in the Code of West Virginia which says, "that when one party to a suit is dead the other party shall not testify as to any communications or transactions had with the dead party." The learned judge in this case ruled that the term "transactions" applied to this case; that a surgical operation is a transaction; that the defense could not testify in their own behalf; could not give in detail the conversation which took place in Parkersburg, and which led to the operation; that Dr. A. S. Keever could not testify as to the conversation at his consultation with Dr. Deem two days before the operation, nor as to his examination of the patient at that time, nor as to his diagnosis made at that time; that neither Dr. Harris nor Dr. W. S. Keever could testify to what they said, saw, did, or thought within the room at the time of the operation upon Mrs. Tice, nor was Dr. A. S. Keever allowed to testify as to Mrs. Tice's condition the day after the operation, when he saw her for the last time, nor to testify to any conversation with Dr. Deem at that time. And it was further ruled among other things by the learned judge above referred to that no question should be put to any expert witness that was not based on the assumption that the evidence sworn to by the prosecution was true. The only persons present at the operation besides the doctors were the father of the woman, the grandmother, the husband, and a relative. Dr. Deem swore to certain of these charges as given above, Mr. Scott and Mrs. Canary swore to certain others; the grandmother was not produced as she was said to be out of the State. The husband did not testify as he is administrator of the estate of the deceased, and brought the suit. It was said that if he had testified the defendants might have been heard.

After the trial had continued ten days the jury disagreed, two being for the defense and ten for the prosecution. The case will, of course, be tried over again.

The comments I wish to make are as follows: No physician is safe in practising in West Virginia, if he loses a patient; it matters not whether the case be medical, surgical, or obstetric; if he is sued on the civil side of the court he will not be allowed to testify in his own behalf. If he is fortunate enough to be sued for a criminal act he

may testify; no evidence of skill, ability, or experience will avail him, for the court holds that "The greater the ability and the more the experience the greater the responsibility." No legal process can be drawn that will relieve doctors from responsibility. The only help is to take disinterested witnesses to all surgical operations and cases of labor, or cases of serious illness, or to trust to the next Legislature to amend the law, or to give a different construction of the word "transactions" in the law referred to.

NOTE.—This case was again called for trial at the ensuing November term of the court. At that time the judge who had presided at the original trial was dead, and not one of the original attorneys in the case appeared for the plaintiff. He was represented by the stenographer of the original trial, and he pleaded that "he was unprepared for the trial and had not a witness present." The case was thrown out of court. During the session of the Legislature of 1897 the law was so amended as to allow physicians to testify in their own behalf. This same law, just as it was in West Virginia before being amended, is in the codes of a number of other States—notably in New York—a menace to all practitioners of medicine and surgery.

MEDICAL PROGRESS.

Rupture of the Callus in Fracture of the Patella.—BEGOUIN and AUDERODIAS (*Gaz. méd. de Paris*, October 23, 1897) have collected some of the published reports of fractured patellæ treated by the method advocated by Tilanus, *viz.*, by massage and early movements. They find that of thirty patients so treated, no less than seven suffered the accident of refracture through the callous. This percentage is so high that it must be taken into account in deciding on the best method of treatment of this condition. The two procedures which are to-day attracting the attention of surgeons are the methods of Tilanus, and the osseous suture. In point of view of rapidity of cure the former must give place to the latter; and when to this disadvantage is added the refracture of the callous in almost every fourth case treated by massage and early motion, the suture must be regarded as the method of choice.

A New Radical Operation for Inguinal Hernia.—BERNHARD (*Correspondenz-Bl. f. Schweiz. Aertzte*, November 1, 1897) advocates a new operation for the radical cure of inguinal hernia. The departure from previous operations consists in the separation of the testicle with its cord, the ablation of the tunica vaginalis, and the return of the organs in question to within the abdominal cavity, outside of the peritoneum. When this is accomplished, the accurate closure of the inguinal canal is comparatively a simple task. Bernhard has performed this operation upon two patients, each time with success. He has, of course, no means of knowing what the fate of the transplanted testicle may be. As a disadvantage of this method is mentioned the difficulty of diagnosis in case of a subsequent development in the transplanted testicle of such diseases as attack this organ, for instance, syphilis, tuberculosis, carcinoma, sarcoma, cysts, etc. A warning is given to those who perform this and other hernia operations to avoid, if possible, dividing the skin of the scrotum, as the probability of primary union is thereby much diminished.

Formula for Home Modification of Milk. — WESCOTT (*Archiv. of Pediat.*, January, 1898) is of the opinion that mixtures of cream and whole milk are more reliable and accurate than mixtures of cream and under-milk. He suggests the following simple and practicable formula:

Cream (12 per cent.) -	7 ounces, 2 drams
Whole milk - -	8 ounces, 1 dram
Lime water - -	2 ounces
Sugar of milk (dry) -	1¾ ounces
Water - - -	22 ounces, 5 drams.

This formula will give forty ounces of a mixture containing three per cent. of fat, six per cent. of sugar, and 1.5 per cent. of proteid. The advantage of a formula of this sort is that the fat and proteid may be gradually increased or diminished without frequent changing of the whole formula. To do this it is simply necessary to alter the amount of milk and cream in the mixture. Thus, in normal cases, a half ounce of milk may be added, that is, a teaspoonful more each day for four days in the week, this quantity to be maintained for the balance of the week. Then, if digestion is not disturbed the same increase may be directed for the next succeeding week, or possibly it may be necessary to omit the increase for a week—according to the condition of the child.

Disinfection of Houses with Formaldehyd. — JOHNSON (*Brit. Med. Jour.*, December 25, 1897) has obtained good results in disinfection of rooms by formaldehyd, liberating the gas under pressure from a mixture of equal parts of formalin, and twenty per cent. calcium chlorid solution. He has found formaldehyd lamps unsatisfactory. He also found it necessary to use larger quantities of formaldehyd than are generally advised, the best results being obtained upon using one pound of formaldehyd per 1000 cubic feet to be disinfected. At a cost of from twenty-five to thirty cents per pound the expense of disinfecting in this manner is not great for private houses. He made a number of experiments to determine the penetration of the gas in absolutely tight chambers, and in those having ordinary cracks. As a result, he has found it more serviceable to generate an excess of the vapor rather than to paste up cracks, though no large crevices or drafts should be permitted. For smaller articles the use of a portable chamber made of "enameled duck" having a projecting flap around the open end so as to be rolled up, with a corresponding flap of the cover, gave him good results.

On the Duration of Life of Epithelial Grafts.—WENTSCHER (*Centralbl. für Chir.*, January 8, 1898) has conducted experiments to determine the length of life of epithelial grafts outside the body. He preserved the grafts either in normal salt solutions, or dry, in sterilized gauze.

Later, these grafts were transplanted upon suitable surfaces (usually prepared by excision), such as granulating ulcers of the leg. The oldest graft which grew was twenty-two days old. Grafts which had been preserved

dry for four weeks showed no evidences of growth after transplantation. Cold had very little effect upon them. It was found that grafts which had been kept frozen for fourteen hours, when thawed and placed upon a suitable surface grew without difficulty. Heat was more disastrous, a temperature of 50° C. (122° F.) in one case prevented the subsequent growth of a graft. Grafts are very easily affected by chemic influences. Even weak antiseptic solutions prevented their subsequent growth in every case, with one exception.

Soap as a Disinfectant.—Talbot (*Diatet. and Hygien. Gaz.*, January, 1898) reviews the work of various experimentors and shows that soft soap in one-per-cent. solution is a valuable disinfectant for bacillus anthracis, cholera germs, for the bacteria of typhoid fever, and also for bacterium coli. Care, however, should be taken in the choice of potash soaps. The ordinary soft soap of commerce is often extremely unclean and possesses very little value. It is necessary to use a strong solution, and to wash the hands thoroughly with plenty of soap and water. Unfortunately, soap has no effect upon pus cocci. Almond soap was found to be more powerful than other varieties experimented with. It was also shown that soap containing antiseptics, *viz.:* benzol, carbolic acid, has less antiseptic power than the same amount of these substances without the soap. Therefore, the practice of manufacturing soaps with the addition of disinfectants is not founded on rational principles. The proper method of disinfecting the hands must still continue to be, first, washing them with soap, and afterward with the selected disinfectant.

Purulent Inflammation of the Fat Capsule of the Kidney.—Maass (*Centrabl. f. d. Grenzgebiete d. Med. und Chir.*, December, 1897) draws some interesting conclusions from twenty-two cases of purulent inflammation of the fat capsule of the kidney. In all of these the perinephritic abscess was secondary to suppuration elsewhere. The source was usually in the kidney itself, although sometimes it was in an inflammation of the connective tissue of the pelvis. Such abscesses may also be secondary to inflammation in the thorax. The clinical symptoms are those of abscesses in general: fever, localized pain, pressure upon the colon, etc. The diagnosis is, in most instances, easy to make, especially if a tumor has formed in the lumbar region, or if edema of the skin presages the approach of pus; but in the very beginning of the trouble the diagnosis may be most difficult, even impossible. Treatment consists in evacuation of the pus by means of the most convenient incision. This is usually found to be an oblique one, beginning in the angle between the twelfth rib and the quadratus lumborum muscle and extending downward and forward a distance of seven or eight inches. The prognosis after operation is good. Sixteen of twenty-one patients treated by this method recovered.

Chronic Proctitis.—Talley (*Mathews' Quar. Jour. of Rect. and Gastro-Intes. Dis.*, January, 1898) regrets that chronic proctitis has not yet received the study and attention which its importance demands. He insists that the only proper method of making a diagnosis of a rectal affection is by means of direct inspection. The use of Kelly's proctoscope, with a strong reflected light, will clear up many obscure cases. This instrument is better than a speculum and is less painful. In examination with a proctoscope the mucous membrane closes uniformly over the open end of the instrument as it is withdrawn. The patient may be placed in the lithotomy or knee-chest position, the latter being preferred when high examinations are to be made. Gonorrheal proctitis is common in prostitutes, the discharge from the vagina easily infecting the rectum, but is not found in men unless they practise pederasty. Non-specific chronic proctitis may occur as an acute inflammation, as a superficial ulceration, as a papillomatous vegetation, or it may involve the submucous tissue, causing proliferative stenosing proctitis. The main symptom of this former variety is slight tenesmus, with frequent mucopurulent stools, at times streaked with blood. The patient should be put to bed, and placed upon a bland diet. The sphincter muscle should be divulsed, and the ulcerated mucous membrane touched with a strong solution of nitrate of silver. The rectum should be irrigated daily with warm boric-acid solution. Injections of sweet oil and iodoform, and the introduction of suppositories of iodoform and boric acid are also grateful to the patient.

Proliferative stenosing proctitis never heals of itself. It may be treated palliatively by means of dilatation with rubber bougies, passed at intervals, though not oftener than every five days. If the stricture is very resistent an internal proctotomy should be performed to facilitate dilatation. This is an operation practically without danger when the stricture is not more than two inches above the external sphincter muscle. After division of the stricture divulsion of the rectum should be performed, and elastic bougies should be passed from time to time to avoid recurrence of the stenosis.

Recent Observations upon Cocain Poisoning.—Griffin (*Phil. Med. Jour.*, January 8, 1898) calls attention to the variety of susceptibility and idiosyncrasy to cocain which different individuals present. Some patients who are acutely poisoned exhibit maniac excitement, while others are stupid. It is well known that poisoning has followed the use of a dose far short of the maximum therapeutic allowance, even .077 of a grain having caused serious symptoms. There are also instances in which a solution of a certain strength has been used without unpleasant effects, while a repetition of the same dose on a subsequent occasion has caused toxic symptoms. The injection of camphor dissolved in ether and the employment of artificial respiration have recently been extolled as the best treatment for the acute poisoning.

In chronic poisoning by cocain there is one symptom known as Magnan's sign, which is of considerable importance in establishing a diagnosis when the use of the drug is denied, and is also of importance in other cases as indicating to the physician the necessity for immediate discontinuance of the remedy. This sign is a hallucination of sensation, the patient complaining of feeling some foreign body beneath the skin. This is generally described as being small in size, and is usually ascribed to the presence of "sand," "worms," or "microbes."

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, FEBRUARY 19, 1898.

THE NEW YORK CITY BOARD OF HEALTH AND THE BRUSH BILL.

IN last week's issue we had occasion, in connection with the bill before the Legislature restricting the powers and acts of the Board of Health of New York City, to comment in general upon the excellence of the work of this board and the credit it had reflected upon the community and the country. One feature of the bill, that bearing upon the management of pulmonary tuberculosis, was treated in detail. Judging from the notices in the secular press and in some contemporary medical journals, there apparently exists such a shadowy notion in regard to the provisions of the Brush Bill that it seems wise to present more in detail the main features of this measure.

1. The clause in the former bill restricting the presidency of the Board of Health to a layman is stricken out, thus opening the possibility of that office being occupied by a member of the medical profession, although the health-officer of the port is debarred from holding the position. This provision seems eminently wise. There is no reason why the president of the board should not at times be a physician.

2. The board is reduced to five members, consisting of the health-officer of the port and four commissioners appointed by the mayor, two of whom shall be physicians. The president of the police board, who was formerly a member, is thus excluded. This provision is of little moment, and is as unnecessary of discussion as it was of insertion in the bill.

3. The term of service is changed from six to four years. This brings the tenure of office in correspondence with that of the mayor, and so savors more of politics than of statesmanship.

4. The clause empowering the board to produce diphtheria antitoxin or other antitoxins is stricken out, and all authority to relieve, by antitoxin treatment, persons suffering from diphtheria or other infectious disease is omitted, as well as the power of disinfection in these diseases. The cunning hand of some ardent opponent of antitoxin seems to be apparent here. As we read the revised bill, no authority to produce, to use, or to distribute antitoxin is given the board. Indeed, all detailed reference to diphtheria is stricken from the law, the disease simply being mentioned as one of the infectious, contagious, or pestilential diseases. What more startling announcement could come thundering in the ears of an intelligent community, to say nothing of those interested in and conversant with sanitary measures, than that there has been taken away from the sanitary authorities and the medical profession in conjunction therewith, the power and the privilege of reducing the death-rate of diphtheria in New York City from 35.2 per cent. during the four years preceding 1895 (when antitoxin was first employed) to 16.3 per cent. for the three years following that period, and to 14.6 per cent. during the year 1897? The medical profession of the city has come to rely so implicitly upon the diphtheria antitoxin of the Board of Health that during the past year 1100 cases of diphtheria were treated without charge by the Board of Health at the request of the attending physicians. These patients were reported by the physician in charge as being too poor to pay for his visits.

5. The power to afford gratuitous vaccination to and among the poor is retained, and the board is empowered "to procure and preserve pure vaccine lymph or virus." No authority is given to produce vaccine lymph, and yet, as shown in our editorial of last week, the Board of Health, by experimentation in its laboratories during the year 1896, brought

vaccine lymph to a higher standard of perfection than was previously known.

With all due consideration of the economic principle that subsidized institutions should not be allowed to compete with private enterprise, and with all respect to the private commercial drug-houses who supply the profession and the community with other high-grade pharmaceutic preparations, we would submit the proposition that in an enterprise involving so much scientific experimental work and in which so much is at stake, involving an almost complete revolution in the principle of therapeusis, an exception can justly be made. We trust, however, that the time is not far distant when the art of producing biologic products will have reached such a definite, settled basis as will permit commercial competition to be a sufficient motive, not only to maintain but to advance the excellence of these preparations. It is to be hoped also that when that time arrives sufficient public funds will be placed at the disposal of the Board of Health to enable it to carry on its laboratories without the necessity of selling any of its products. By private letters received from the H. K. Mulford Company and from Parke, Davis & Company assuring us that they are now producing the most highly concentrated product that has ever been offered to the medical profession, the realization of hopes in the direction referred to seems already at hand.

6. Every physician is obliged to report every birth occurring in this city at which he may be present under the penalty of a fine of $100. This is an apparent injustice. Physicians are frequently called to poor women for the purpose of correcting some malposition in obstetrics, for which they receive no remuneration whatever, and yet they are obliged to be at the expense and trouble of reporting such births or be fined $100. In England a fee of $1 is allowed for every birth reported.

7. On the same penalty for omission, physicians are required to report all cases of infectious, contagious, or pestilential disease within twenty-four hours after the nature of the disease is ascertained or suspected. The following diseases are named as being embraced in this classification: Measles, diphtheria, scarlet fever, smallpox, chickenpox, typhoid fever, typhus, cerebrospinal meningitis, Asiatic cholera, and yellow fever. Evidently the intent of this clause was to exclude pulmonary tuberculosis, but, in doing so, as was pointed out in these columns last week, a number of well-recognized infectious and contagious diseases have been omitted.

Several other minor changes have been made in the wording of the bill, but the provisions already mentioned are the principal ones requiring attention. With the exception of the clause first named, they all show ill-considered preparation and in their entirety so restrict the sphere of action of the health authorities as to menace the welfare and health of the community. The bill should be withdrawn.

WHAT'S IN A NAME?

IT is a phrase often quoted that the rose by any other name would smell as sweet, and this saying not only has the advantage of being ancient but likewise truthful. Many persons interested in the development of a health service in this country have expressed a well-meaning and undoubtedly honest objection to the name of the Marine Hospital Service as indicative of a service caring for the public health.

It is true that the name Marine Hospital Service does not indicate specifically all the functions which this department performs. It was baptized 100 years ago by our respected forefathers, and that they did not have the gift of foresight and prophecy is not extraordinary. It is not always that christening produces results which entirely suits later conditions of life. A child may be baptized Napoleon Bonaparte Smith, and turn out to be a character more befitting the name of Peter Cooper Smith. The fact that he was christened Napoleon Bonaparte does not necessarily mean that he is expected to pass through the world performing the same sort of volcanic upheavals as his namesake, but it none the less cripples him in the performance of duties to which he is by training and instinct better fitted. The growth and development of the Marine Hospital Service in the line of its work as a public health service has been gradual and satisfactory. Were it specifically named The Public Health Service a closer designation of one of its important functions would probably be attained, but that it is not so designated is not an insuperable objection to its continuing in the performance of work which it has satisfactorily accomplished in the past, and is performing with equally good results in the present.

The health interests of Great Britian are under the supervision of the Local Government Board, a title which no one will claim indicates just what its duties are, but there seems to be no demand in England for a change of this title so long as the work is properly performed. The Department of the Interior scarcely describes the variety of work which is continually and satisfactorily being performed under this name. No one seriously undertakes to suggest changing the name of this department of the Government, because the title does not accurately express all its duties. In fact a common instance of misapplication of names is the term "quarantine service" or "quarantine station." This term originally meant a forty-days' detention of ships or persons coming from infected places, a regulation which does not exist at the present day, and has been entirely superseded by modern and intelligent methods of disinfection and control. It would be better to substitute another word for this wherever it occurs, but it has become so fixed in our vocabulary that its eradication would be impracticable.

The Marine Hospital Service is an old organization, and has made its reputation under its present name. The public are so used to it that if it were sailing under another name they would have to become educated to the fact that it was not a new organization that was doing its work. It is known from Maine to California and from the Lakes to the Gulf, as our political orators would say. There is no demand for a change of name, and but for the fact that it has been suggested by interested and well-meaning gentlemen who think it is a serious obstacle to the Service becoming the representative health organization of the country, it seems to us that the objection is unimportant, and has no bearing upon the real question. The Service performs its duties satisfactorily considering the limited powers at present entrusted to it, and so long as it does this there need be no discussion as to the colors under which it sails.

ECHOES AND NEWS.

A Medical Senator.—Dr. Samuel Pozzi, the eminent French gynecologist, has been elected Senator for Dordogne.

The Registration of Midwives.—Meetings in support of a bill providing for the registration of midwives are being held in various parts of England.

Fees in Insanity Cases.—In Kansas, jurors who serve in cases in which the sanity of an individual is to be determined, do not receive a fee unless they find a verdict of insanity.

Motor-Cradles,—The latest scientific addition to the nursery is the motor-cradle. It is a question, however, whether babies should be rocked either by machinery or by hand.

Typewriters' Cramp.—According to the *Phonetic Journal* one of its correspondents is suffering from this new form of occupation neurosis as a result of a too assiduous use of the typewriter.

Appointments at Mt. Sinai.—At a meeting of the Board of Directors of Mt. Sinai Hospital, New York, held February 13th, Drs. Morris Manges and Nathan E. Brill were appointed Visiting Physicians to the hospital.

Department of Hydrophobia.—A department of hydrophobia, similar to the Pasteur Institute in Paris, is to be added to the Institute for Infectious Diseases in Berlin, of which Robert Koch is director.

Deportations from State Hospitals.—During the past year the New York State Commission in Lunacy has sent to other States and countries 110 alien and non-resident inmates of the New York State hospitals.

Individual Drinking-cups.—The Columbus (Indiana) Health Board has issued an order requiring the pupils of the public schools to provide themselves with individual drinking-cups. The board is also in favor of individual communion services.

The American Medical Association and Dr. Busey.—Dr. Samuel C. Busey of Washington, who was appointed to deliver the address on State Medicine before the American Medical Association in Denver, has resigned the appointment on account of ill-health.

Medical Popes.—According to the *British Medical Journal*, several of the Roman Pontiffs were students of medicine in their youth, and one, John XXII., who reigned at Avignon from 1316 to 1334, was a qualified doctor according to modern ideas, and wrote medical works.

Louisiana's New Board of Health.—Governor Foster recently announced the appointment of the following gentlemen as members of the new State Board of Health: Drs. Edmond Souchon, John J. Castellanos, L. F. Reynaud, Luther Sexton, H. S. Lewis, Messrs. S. O. Thomas, J. W. Castles, J. D. Hill, and J. C. Denis.

Second Quinquennial Prize.—The second quinquennial prize of $1000 dollars will be awarded on January 1, 1900. This prize, under the will of the late Samuel D. Gross, M.D., is to be awarded every five years to the writer of the best original essay upon some subject in surgical pathology or surgical practice founded upon original investigations. The candidates must be American citizens.

Another Verdict for a Hospital. — Justice Stover, in the Supreme Court, New York City, recently dismissed a suit brought against the Montefiore Home by Alexander Burshell for $100,000 damages for the death of his son who was killed by falling through the elevator shaft while a patient at the Home. Justice Stover held that charitable institutions are not responsible for the acts of their employes.

Tennessee State Board of Health.—The death of Dr. J. Berrien Lindsley, as formerly announced, left vacant the responsible position of secretary of the State Board of Health, with which organization he had been connected many years. Dr. J. A. Albright, at that time president of the board, we learn, has resigned his office and has been elected to succeed Dr. Lindsley. Dr. Albright has our congratulations and best wishes.

Unmerited Criticism.—The *New York Medical Journal* calls attention to the fact that the *Journal de Médecine de Paris* for January 16th states that Mr. Cornelius Vanderbilt has employed Dr. Jean Charcot as his physician for a cruise upon his steam yacht, and remarks that it thinks Dr. Charcot does not do great honor to his father's name by accepting a place as physician and nurse which would be more suitable for an indigent student.

Opposition to the Dispensary Bill.—At a conference of representatives of dispensaries of Greater New York recently held, the bill to regulate dispensaries, now in the hands of the Committee on Cities, was opposed as being harmful and unwarranted. A resolution in opposition to the bill was carried by a vote of 41 to 2, the representatives of the Northeastern Dispensary and of the East Side Dispensary, respectively, alone voting in the negative.

The Brush Bill Condemned by Central Labor Union.—At a recent meeting of the Central Labor Union of New York, one of the delegates attacked the bill which cripples the work of the New York Board of Health by prohibiting the manufacture and sale of vaccine virus and antitoxin. He characterized the bill as vicious and a direct blow at the praiseworthy and successful efforts of the Board of Health in keeping down the death-rate. A resolution condemning the bill was passed, and it was ordered that a copy of the resolution be sent to each member of the Legislature.

Dr. Weir Mitchell's Novel.—According to the *Bookman* Dr. Mitchell's book "Hugh Wynne" is about the second in popularity at the present time. A review has appeared in the *Friend's Intelligencer* of Philadelphia, and also in pamphlet form, the avowed object of which is to correct some of the descriptions given in Dr. Mitchell's book of the manners and customs of the Friends at the time of the Revolution. The resultant of this is a sketch of the old-time Quakerdom of the City of Brotherly Love which might never have been brought out had it not been for the "mistakes" of Dr. Mitchell.

Obituary.—Dr. John Cronyn, one of Buffalo's prominent physicians, died there February 11th. Dr. Cronyn was born in Ireland, obtained his degree of M.D. at the University of Toronto, and settled in Buffalo in 1859. He was an ex-President of the Medical Society of the State of New York.—Dr. George C. Briggs, a prominent Vermont physician, died in his carriage of heart disease, at Burlington, Vt., February 11th. Dr. Briggs was sixty-eight years old, was graduated from the University of Michigan School of Medicine, and for ten years was Professor of Materia Medica in the University of Vermont.

Kipling's Estimate of American and Other Practitioners.—Rudyard Kipling, the poet novelist, in an after-dinner speech at a banquet given in London to Sir William Gowers not long since, paid a graceful tribute to the heroism of the medical fraternity. He had mixed with doctors, he said, the world over, and had seen them going to certain death with no hope of reward. He had seen them handling cholera and smallpox, and, when dying therefrom, telegraphing for a substitute. He had seen them, in America, manage a practice twenty miles in each direction, driving horses through eight feet of snow to attend an operation ten miles away, digging their horses out of the snow and then proceeding on their way. Mr. Kipling declared that it was one of the proudest things of his life to have been associated with "real fighting men of this class."

Charity Abuses in Michigan.—Recent information from Detroit leads to a belief that an earnest effort will be made there to combat the growing dispensary evil. In this respect, as in many others, New York has set a good example, which we are glad to know is being followed by our brethren throughout the country; though it is to be hoped that they will not injure the prospects of reformatory measures by an internecine strife such as at present characterizes the position of New York physicians on the question of a bill to abolish medical charity abuses—a measure of such vast importance, not only to physicians, but, on a general economic basis, to the people at large. In Michigan the abuse referred to seems especially rife in the free dispensary of the University Hospital at Ann Arbor, and it is against this institution that criticism is particularly leveled.

The Marine Hospital Service and National Quarantine.—It is somewhat gratifying, after several months spent by the MEDICAL NEWS in presenting the various aspects of this subject, to note that the *New York Medical Journal* and the *Medical Record* have rallied to the support of the Marine Hospital Service and united with the MEDICAL NEWS in indorsing the Caffery Bill establishing a National Quarantine in charge of that department of government. The quarantine convention recently held at Mobile, Ala., discussed the various phases of quarantine in detail, but failed to pass a resolution indorsing any of the bills now before Congress. Doubtless the discussion in the convention was a source of enlightenment to the various interests represented regarding the necessity of uniformity in law and practice.

Smallpox in North Carolina.—This disease has been hovering along the southerly borders of the "Old North State" for several months. It has been said that as many

as thirty Georgian counties have been infected; the disease has also made its appearance at Rock Hill, S. C., but it was not known until quite recently that a case had entered the North State. That case was at last brought into Wilmington, in the person of a colored train-hand, whose "run" took him frequently into South Carolina. The editor of the *Bulletin* of the State Board of Health, Dr. Lewis, sounds a note of warning to the local health authorities that the time has come for each and all of them to proffer free vaccination in their respective precincts. He further remarks that the number of persons in that State who have never been vaccinated at all is so great that he and other sanitarians view the situation with alarm.

Dr. Kelsey and the Post-Graduate.—Dr. Charles B. Kelsey of New York recently applied to the Supreme Court of the city for a writ of mandamus directing the Board of Directors of the New York Post-Graduate Medical School and Hospital to reinstate him as professor of surgery in that institution, a position which he held from March, 1890, until January 27, 1898, when he was removed without a hearing by the Board of Directors of the institution. Charges of disloyalty toward the hospital had previously been preferred against him. Dr. Kelsey was removed by a vote of 6 to 1. The by-laws provide that a vote of three-fourths of the board, which numbers eleven, is necessary for a removal, so the question of the legality of the removal rests upon whether this means three-fourths of the whole Board, or three-fourths of those present and voting. Decision was reserved.

CORRESPONDENCE.

THE DISPENSARY BILL.

To the Editor of the MEDICAL NEWS.

DEAR SIR: Your allusion in a recent issue of the MEDICAL NEWS to my opposition to the Dispensary Bill seems to call for a reply on my part; indeed, I am glad to have this opportunity to place this bill before the medical profession in its true light.

In the first place, you are mistaken if you think the Chairman of the Legislative Committee of the Medical Society of the State of New York is the only person opposed to the measure under consideration, for my action is endorsed by the whole committee, by the officers of the State Society, and by the majority of the medical men of the State. It is safe to say that not one-fourth of the profession of the city of New York would endorse this bill if its true character were known; I doubt very much if you would. Let me place before you some of our objections to it:

This bill provides that after its passage all dispensaries must make application in writing, accompanied by such statements, verified by oath, as may be necessary, to the State Board of Charities for a license. If this board believes that the operations of said dispensary will be for the public good a license shall be issued; "but that no dispensary shall enter upon the execution, *or continue the prosecution* of its purpose unless licensed in this way."

The bill gives the State Board of Charities absolute power to make such rules governing dispensaries as it may deem proper, to alter or amend the same at will, and to revoke licenses at pleasure. In other words, it takes away from the medical profession and the Boards of Managers of all dispensaries in the State of New York any voice in the management of these institutions, and vests this power in a State Board, political in its character and subject to change at any time. Now we ask you and we ask the medical profession if this is just? Is this what we have been striving for for several years?

What would be the effect of a law of this kind? Under Chapter 771, Laws of 1895, the State Board of Charities has the right to maintain a general supervision over all institutions of a charitable or eleemosynary character, incorporated or unincorporated, whether State, county, or municipal, and to call upon the Attorney-General of the State, or the district attorney in any county, to enforce its rules; further than this no institution can receive money from the county or State if the State Board of Charities objects. Is this not power enough? With all this power, the State Board of Charities has done little or nothing! If the present dispensary bill should become a law is there any reason to suppose they would do any more? The law would in all probabilities become a dead letter, and the medical profession, instead of being benefited, would be prevented from doing anything further in its effort to remedy dispensary abuses. On the other hand, the State Board of Charities could, on October 1st, close every dispensary in the State of New York. When it comes to dispensaries in drug-stores and tenement-houses, we have little to say. If it is in the interest of the public to close them, we would be willing to assist any effort in that direction, but we will oppose to the end any effort the consequences of which would be to place a weapon so terrible in the hands of any State board. The dispensaries in the State would be in a constant condition of uncertainty, which would seriously cripple their usefulness; trust moneys, instead of being used to benefit the poor, would be diverted to purposes for which they were never intended; *i.e.*, defraying the expenses of endless litigations, and in the end the medical profession would receive the contumely it would deserve if it allowed so pernicious a measure to go unchallenged. The question is naturally asked if there is no way in which this matter can be adjusted, and in answer I beg to refer the members of the Medical Society of the County of New York to the minutes of the meeting of May 24, 1897. It is recorded that over seventy-seven per cent of institutions of this city expressed their willingness to correct any abuses that might exist in the dispensaries. Let the medical profession of the State, through representatives of the State and county societies, get together and confer with the boards of managers of the various institutions, and with the State Board of Charities if necessary, and there is no doubt a satisfactory solution of this vexed question could be found which would be just to all concerned.

I believe I have said enough to show my position in this matter, but I voice the sentiment of the Legislative

Committee, if referred to, when I say that we feel that we would be false to the trust imposed in us if we did not protest against a bill so manifestly unjust to the medical profession and to the community at large as the present Dispensary Bill.

Very truly yours,

FRANK VAN FLEET,

Chairman of the Committee on Legislation of the Medical Society of the State of New York.

116 EAST EIGHTY-SECOND STREET,
NEW YORK, February 7, 1898.

VIBRATORY THERAPEUTICS.

To the Editor of the MEDICAL NEWS.

DEAR SIR: My attention has been called to a historic article on vibratory therapeutics from the pen of Dr. Frederick Peterson which appeared in a recent issue of the MEDICAL NEWS. Doubtless in the preparation of his article the writer was ignorant of the fact that in the second edition of my work upon nervous diseases (H. C. Lea's Sons, 1881) I described and depicted a vibrator of my invention which I had used since 1879. This, so far as I know, was the first *percuteur* in which electricity has been employed, and is, I believe, to-day the best, because of the fineness of its vibrations. Some years ago I purchased a motor instrument from Gaiffe of Paris, which is more compact than those the Doctor describes, and this, too, he appears not to have seen. After many years use of vibratory therapy I am now convinced that its value its greatly exaggerated, and depends more upon the creation of suggestion than anything else, in which conclusion I think I am supported by Dr. Dana, who has gone fully over the ground. This form of treatment has been so popular with hypochondriacs that a few years ago a company with a large capital was formed here to exploit a "household" vibrator, of which nothing is now heard.

ALLAN MCLANE HAMILTON, M.D.,

44 EAST TWENTY-NINTH STREET,
NEW YORK, December 29, 1898.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

THE INVESTIGATION OF HOSPITALISM—CONTAGIOUS DISEASES DURING 1897—THE STATE QUARANTINE—PHILADELPHIA HOSPITAL'S NEW BUILDING—THE DELIVERY OF MILK IN SEALED JARS—LUCIEN MOSS HOME FOR INCURABLES—MASS-MEETING IN FAVOR OF THE FILTRATION BILL.

PHILADELPHIA, February 12, 1898.

IT is difficult to conceive a more complex undertaking than the effort, now in its inception in this city, to eliminate "hospitalism." If undertaken in a spirit of fanaticism directed toward hospital physicians as a class, as seems the inclination of some agitators, the movement must surely stir up such hostility among this class of the medical profession that cooperation will be impossible, and the outcome will be profitless. On the other hand, if undertaken with conservatism and with the help of representative local medical societies, the evil may be remedied to the satisfaction of all. The movers in this pending attempt at reform must necessarily represent all classes of respectable regular physicians—the general practitioner, faculties of the medical schools, and the physicians connected with the various city hospitals. The officers of the Charity Hospital, who are the prime movers in this inquiry into the question of indiscriminate free treatment by hospitals, are inclined to adopt a rational and sensible method of procedure, by inviting the attention of the County Medical Society to their plans, and by asking this body to act with them in the matter. This is to be done at the next meeting of the Society, on February 23d, until which time the precise method of beginning the investigation must remain a matter of conjecture. Meanwhile, the daily press is taking up the matter, and throws open its columns to every one who may choose to express his views, with the result that fictitiously signed letters from holders of medical degrees (?) have begun a tirade against hospital physicians which cannot but reflect unjustly upon the objects of their disapproval; for how is the newspaper-reading public to discriminate in a matter of this sort? Undoubtedly hospital abuses exist, but they should be remedied by the profession itself, and an editorial throttle should be applied to the rantings of the many disgruntled correspondents whose anonymous expressions only retard real progress toward a solution of the difficulty, and help to breed in the minds of an impressionable public a preconceived biased view of the actual situation. Apropos of this topic, it may be remarked that Director Riter, of the Department of Public Safety of this city, has written to Dr. Frederick Holme Wiggin of New York demanding an explanation of a charge that "in some instances policemen are paid $1 or $2 for each patient they bring to the hospital," made by Dr. Wiggin in his address on the hospital question at last week's meeting at the Charity Hospital. The outcome of this will be watched with interest, for the charge has caused a sensation in local medical circles and in the police department.

The annual report of Dr. William M. Welch, physician in charge of the Municipal Hospital for Contagious Diseases, shows that during the year 1897 more patients were admitted to the hospital than during any previous year in its history, the number exceeding even the totals of 1871 and 1872, when smallpox was very prevalent here. Dr. Welch attributes this increase not to an extraordinary prevalence of contagious diseases last year, but to the strict enforcement by the health authorities of the law requiring the placarding of infected houses, with the alternative of removal of the infected inmates to the city's hospital, and to the growing popularity of this institution. The incease in the number of admissions to the Municipal Hospital during the last eight years is shown by the following summary: 1890, 52; 1891, 127; 1892, 480; 1893, 524; 1894, 810; 1895, 1191; 1896, 1252; 1897, 2179.

The quarantine officers of this State are protesting against the passage of a bill now before Congress which, should it become a law, would seriously interfere with the power of State quarantines, by allowing a vessel

to enter port with a clean bill of health from the government quarantine officials, regardless of the certificates of the State and local authorities. Inasmuch as the Pennsylvania State Quarantine Service has proved its usefulness in numerous instances in which the government officers have passed vessels requiring a later detention, it does not seem that the passage of this pending bill is quite justified. Philadelphia, at any rate, does not feel that the power of her State and city authorities should be curtailed in such a summary manner.

The Board of Charities are endeavoring to secure for immediate use an appropriation of $60,000 from Councils to complete the new additions to the insane department of the Philadelphia Hospital. This sum, which, like the filtration bill is delayed by councilmanic inactivity, is urgently needed to provide heating apparatus for the new building, which cannot be occupied until this provision is made. The new building will afford accommodations for 1400 patients, while the present quarters of the insane department, which are intended for but 1050 inmates, actually contain 1340.

Arguments for and against the practice of delivering milk to customers in sealed glass jars, now largely adopted here, took place this week before the Board of Health. The question arose from a petition recently presented to the board by a local dairymen's association, asking for the passage of an ordinance prohibiting the distribution of milk in glass jars, on the ground that this custom tends toward the dissemination of disease. Thus far, the evidence produced by the complainants has not been of a very convincing nature, when opposed to arguments in favor of the glass-jar system by such authorities as Mr. William Gordon of the Walker-Gordon dairies; Dr. J. Cheston Morris, whose dairy-farm in Chester County is considered a model of its kind; Dr. Meade Bolton, of the New Jersey State Laboratory of Hygiene; and Dr. Ravenal, Bacteriologist of the Pennsylvania State Live Stock Sanitary Board. Another hearing will be given the oppositionists at a later date, and the Board of Health promises to make a thorough investigation of the whole matter before delivering an opinion.

The erection of the buildings of the Lucian Moss Home for Incurables of the Jewish Hospital will be commenced within a short time, the present delay being due to the auditing of the accounts of the donor, whose will is still under legal consideration. The Jewish Hospital received last week a gift of $10,000 to the endowment fund of the institution, in memory of the late Ida M. Fleisher.

That the people of Philadelphia have awakened to the fact that something must be immediately done to provide a pure water-supply was amply and emphatically demonstrated at a mass meeting held at Horticultural Hall, on February 12th, under the auspices of the City Organizations' Committee, for the purpose of forcing Councils, through public opinion, to remedy the trouble by at once passing a bill creating a loan for the establishment of a filtration-plant. Representatives from all classes of citizens were present at this meeting, and definite demands were made that immediate steps be taken to eradicate the present typhoid epidemic by providing a new water-supply for the city. Members representing the following bodies were present at this popular demonstration: the College of Physicians of Philadelphia, the Philadelphia County Medical Society, the Health Protective Association, the Board of Trade of Philadelphia, the Trades' League, the Civic Club, the New Century Club, the Union Labor League, and many other societies, building associations, and hospitals. Addresses were made by Frank J. Firth, chairman of the committee, by Judge Ashman, by Rabbi Krauskopf, by Dr. S. Solis Cohen, by William Waterall, and by Dr. John K. Mitchell. Resolutions were unanimously adopted for presentation to Councils, urging immediate action for the creation of a loan "for the purification and filtration of the city water-supply, under direct municipal control, ownership, and management, and in no other way." This is the second indication of the popular mind presented to the notice of the city legislators this week. On February 10th, Councils' Committee on Water gave a hearing to the views of representatives of local medical societies and municipal organizations, who joined forces for the occasion, to urge upon Councils the necessity for the installation of a filtration-plant at the earliest possible moment. At this hearing the following organizations were represented: the College of Physicians of Philadelphia, by Drs. John K. Mitchell, A. C. Abbott, and D. D. Stewart; the Philadelphia County Medical Society, by Drs. S. Solis-Cohen, Edward Jackson, and William M. Welch: the Municipal League, by George Burnham, Charles Richardson, Clinton Rogers Woodruff, and Hector McIntosh, and the City Organizations' Filtration Committee, by Frank J. Firth and J. Vaughan Merrick. Views similar to those expressed at the mass meeting at Horticultural Hall were laid before Councils' Committee on this occasion.

OUR PRAGUE LETTER.

[From our Special Correspondent.]

THE GERMAN UNIVERSITY OPENS ITS DOORS ONCE MORE — THE BOHEMIAN UNIVERSITY AND THE CZECHISH MOVEMENT—INFECTIOUS DISEASES IN PRAGUE—THE STATISTICS OF THE PRAGUE MATERNITY IN THE MIDST OF THE PREVAILING UNSANITARY CONDITIONS.

PRAGUE, February 11, 1898.

THE German University opened its doors once more after a six-weeks' interregnum on January 10th. Peace, at least for the time being, seems to have settled down over Prague, and the two universities, the German and the Bohemian, will continue their sessions side by side as before. It is officially announced that a new Czechish or Bohemian university is to be opened in Mähren (Moravia) before the end of the year. Though founded only in 1881 and the medical department only in 1884, the Bohemian University of Prague has now over 2300 students, of whom about 750 are engaged in the study of medicine. It has this large number not because it has attracted students from the German University, for the number of students at the latter institution has only decreased by about three hundred, but rather because the spirit of advance among the awakening Czechish people

has attracted numbers of students to their university. The intellectual enthusiasm so notable among the other Slav peoples of northeastern Europe has touched the Czechs too, and with surprising results. From the medical faculty of the Bohemian University has come during recent years a series of scientific advances which have attracted worldwide attention.

Professor Hlawa's name is well known in pathologic anatomy, and from Professor Horbaczewski has come some of the most striking work of late years in physiologic chemistry. A series of text-books in Bohemian by the medical professors has served to fix the status of the language and give it a place in the scientific world which it did not have before.

The Bohemians insist that their language shall, equally with German, be the language of their courts of law, of government business, and of the officials who caused the late unpleasantness. The means employed—the riotous demonstration, the injury of the property of German citizens, and of the German University, cannot but be universally decried; the movement itself—a demand of their language rights for the sake of their nationality can scarcely fail to elicit sympathy from all sides. The rioting was the work of the ignorant, the mobile vulgus so hard to control, whom a demagogic press had worked to a frenzy because it seemed as though recent laws enacted in their favor might be declared legally inactive. The Czechish movement itself depends for its vitality upon a widely different class—a thoroughly determined, highly intellectual body of men who will not cease their endeavors until they have acquired for their country the autonomy which Hungary enjoys in the Austrian Empire.

Of this body of educated men and zealous patriots many are physicians who have been the apostles of the movement to the country people. Bohemia possesses a very large number of doctors, many of them young. About five years ago, between the Bohemian University with 1200 medical students and the German University with 800 there were altogether 2000 embryo doctors coming into existence each year. All of them were practically from Bohemia, all intending to practice within her borders, and yet Bohemia is but a small country. It can readily be understood then what a large and influential body of patriots they make. An interesting study in supply and demand is the gradual reduction of the number of medical students at both universities, until now scarcely 1000 are here. The number of law students has almost proportionately increased at both universities.

There is a lesson for the antivaccination agitators in the faces one sees so often on the streets of Prague. Much oftener than elsewhere in central or eastern Europe, at least, one comes across faces deeply pitted with pockmarks. Fifteen to twenty-five and more years ago, in the country districts of Bohemia there was great opposition to the enforcement of the vaccination regulations. This was shared in many cases by the natural leaders of the people, the schoolmasters, the local clergy, and the office-holders. The result was as might have been expected, a series of smallpox epidemics, some of them of very severe types.

Gradually the state of things altered. The spirit of advancement among the Czechs led to the general recognition of the foolhardiness of further refusal to accept what the world has long recognized—the immense benefits of vaccination. Curiously enough, the same reformation of feeling has not occurred among certain of the German rural populations, especially near the Bohemian boundaries, and I am credibly informed that now it is among this class of the population that smallpox continues to be more or less endemic; so it is likely enough that the striking lesson of the pockmarked faces in the streets of Prague will continue for some years to be a warning to those who, for reasons which it is not easy to understand, persist in their senseless opposition to vaccination in countries in which it is to be supposed that civilization is far enough advanced for the public to accept sanitary precautions at the bidding of science, and not oppose them for factitious, imaginary, and sentimental considerations.

Here, in Prague the lesson of the benefit of sanitary and hygienic precautions, from their absence, is extremely striking. All the infectious fevers find a place here at almost any season of the year. Typhoid rages because the water-supply is contaminated, and there are always a large number of patients with this disease under treatment in the hospital. Diphtheria and scarlet fever seem especially common, though the former, thanks to the serum treatment (in most cases they administer absolutely no other remedy), now claims less than one-third the number of victims it formerly did.

Owing to the unsanitary, overcrowded, uncleanly condition of the poorer classes, skin diseases seem to take on a special character. Impetigo is very common, and modifies other skin affections to a considerable extent. Rheumatism seems much more than ordinarily frequent. It takes on a great deal more than usual of the character of an infectious disease, and seems to be at times even directly contagious. Slight epidemics of it seem to have come under observation, and the cases are prone to occur in groups with definite relations to one another as regards time and place. Its analogy with pneumonia in these respects would seem to be much more outspoken here than elsewhere in Europe, though most of these peculiarities have been noticed by other clinicians, for instance, Eichhorst and Senator.

Influenza would seem to be endemic here, and cases are observed in the hospital wards every fall and winter, especially in which the diagnosis is made, not from the clinical symptoms and course of the disease alone, though these are extremely characteristic, but from the demonstration of the bacilli in the sputum. On the whole, the hygienic conditions here are just such as prevailed generally in Europe fifty years ago. Determined, well directed efforts which deserve the highest commendation are being made to change this state of affairs. Medical men head the movement, and the most advanced scientific principles are guiding the endeavor. Within a few years the whole aspect of things will have undergone a radical change for which Prague will be indebted to the medical profession. Meanwhile, Prague remains an *argumentum crucis* for the doubters of the

benefits of modern hygienic and sanitary principles and their practical application.

Notwithstanding this utterly unsanitary condition of the poorer classes, Prague has a maternity hospital which can claim favorable comparison with any like institution in the world. With a mortality of considerably less than one per cent. for all cases received, and a morbidity that is wonderfully small, more than 3000 cases of confinement are conducted a year. The material is freely used for teaching purposes, but with such thoroughly antiseptic and aseptic precautions that in whole services of 300 to 500 cases treatment is carried out with total absence of fever, or, perhaps, fever is present only in such cases as have been treated and examined before being admitted to the hospital. The result is all the more marvelous when compared with the extremely high mortality which prevailed before the advent of modern obstetric methods. Prague, with all her disadvantages, continues to be the teacher of the world in obstetrics, and gives besides the striking lesson of how much may be accomplished, even under the most unfavorable circumstances, in ridding labor of its dangers.

TRANSACTIONS OF FOREIGN SOCIETIES.

London.

CYSTIC DISEASE OF THE LIVER AND KIDNEY—SEROTHERAPY OF TYPHOID FEVER — LARGE INTRAHEPATIC CALCULI IN SITU IN A CASE OF DIABETES—CONDITIONS OF THE OCCURRENCE OF LEPROSY IN CHINA AND THE EAST INDIES — PREVENTION OF ENTERIC FEVER.

AT a meeting of the Pathological Society, held December 21st, STILL read a paper on a *case of cystic disease of the liver and kidney in an infant* eight weeks old. He discussed the various theories which have been adduced to account for this condition, and particularly combatted that which ascribes the affection to inflammation. Inflammation of the liver would certainly produce jaundice, and further, the resulting fibrosis would be progressive. The case mentioned was without kidney signs of inflammation. The speaker regarded the condition as due to irregular development, there being overgrowth of the mesoblastic elements of the organ which leads to cystic dilation of the tubules and ducts of the kidneys and liver. ROLLESTON said that no theory would be satisfactory which did not also explain the occurrence of cysts in the brain, pancreas, liver, and kidneys, and he still thinks the inflammatory hypothesis the most satisfactory theory which has yet been advanced. PAYNE pointed out that whichever theory is adopted it is clear that the disease must begin at an early period of fetal life. If the ducts were obstructed just before birth there would be definite symptoms just as in the case of biliary cirrhosis. The process must begin before the secreting and excreting parts are connected.

At the meeting of January 4th, JOHNSON related the history of a case of *cystic disease of the kidneys and liver occurring in a woman aged fifty-three years.* Both kidneys were converted into masses of cysts, varying in size and containing clear or opalescent fluid. The liver was studded throughout with cysts, the largest being the size of a hazelnut. In other respects the liver was normal. The kidneys, however, gave evidence of inflammatory changes, considered by him to be of a secondary character. Johnson thinks that the appearances supported the view expressed by Still at the previous meeting, that the cystic change is to be regarded rather as a developmental error than as a result of inflammation.

AT this meeting BOKENHAM gave an account of researches bearing on the *serotherapy of typhoid fever.* While the serotherapy of diphtheria and tetanus depends upon the existence of a true antitoxic function of the remedial serum, no such function has yet been demonstrated as possessed by any known "antityphoid" or "antistreptococcic" serum, their good effects appearing to be due to bactericidal rather than to antitoxic power. Several methods of immunization have been employed; one consists of the use of virulent cultures; another the use of cultures which have been killed either by chloroform or some other antiseptic substance; a third, and the most satisfactory in some respects, consist of the use of filtrates of cultures grown in albuminous broth, and sterilized by heat.

As a result of his experiments upon horses, Bokenham summarizes as follows: (1) Non-toxic filtrates of fresh cultures have distinct immunizing powers; (2) the immunizing action is displayed toward both living and dead cultures; (3) the serum of an animal treated with filtrates of fresh cultures acquires agglutinative and bactericidal properties; (4) mixed with living cultures in sufficient proportion the serum renders them harmless, and (5) to a certain extent the serum has also protective and curative powers.

ROLLESTON showed large *intrahepatic calculi in situ* from a man, aged thirty-eight years, who died of diabetes and pulmonary tuberculosis, and had been jaundiced. It appeared possible that the extension of duodenal catarrh to the pancreatic duct had produced chronic pancreatitis, and that this in turn had caused diabetes. There were no calculi in the gall-bladder, and the cystic duct was not dilated, so that the intrahepatic calculi must have been formed *in situ.* Intrahepatic calculi existing alone and of large size are rare, as is the existence of cholelithiasis in diabetes.

At a meeting of the Epidemiological Society, December 17th, CANTLIE read a paper on the *physical and ethnologic conditions under which leprosy occurs in China, the East-Indian Archipelago, and Oceanica.* In this part of the world leprosy is essentially a Chinese disease, extending from its focus in the south-eastern provinces to every region visited by the lower class of Chinamen, and to no others. The Japanese, Malays, and some Mongolian races suffer in a less degree, but the aborigines, black and brown, have never known the disease, and, indeed, have in their languages no words for it. A rapid encroachment of the sand from the desert on the cultivated northern provinces of Asia drove the sturdy Manchus southwards, crowding out the weaker Chinamen of the south, and compelling them to seek employment

beyond the seas. The coolies belonging to the poorest classes include many actual or incipient lepers who spread the disease in districts in which it was previously unknown, while the Chinese settlers are solely merchants, planters, or tradesmen. In China itself there are distinct leprous districts, not all of the country being affected. Among the eighteen provinces of the "Middle Kingdom," only six contain such leprous areas. The women of China are themselves active disseminators of the infection, "selling the disease," as they call it, in the belief that they can free themselves from it by coitus with a healthy man.

The Royal Medical and Chirurgical Society, on January 11th continued the discussion of the *prevention of enteric fever*. (See the MEDICAL NEWS, vol. 72, p. 59.) CORFIELD called attention to the fact that mortality from typhoid fever had been enormously reduced throughout the country since the passing of the Public Health Act of 1875, which led to the wide adoption of water methods in the disposal of feces, including the water-closet. London is probably the one city in all England in which water-closets and water-carriage of sewage are most universal, and the death-rate is less for London than for the whole of England and Wales. On the other hand, mortality is highest in the countries in which the water-system least prevails.

Some curious differences between the spread of typhoid fever and cholera are worth noting. Thus Lyons, France, is a town of cesspools, and typhoid fever is always prevalent there; yet, although cholera has been repeatedly introduced, the disease never spreads, and so well recognized is this fact, that the inhabitants of Paris and Marseilles flee to Lyons in time of danger. In his opinion, the air of the houses becomes contaminated from the underlying cesspools, and so favors the occurrence of typhoid fever. SEATON spoke of the reduction of sixty per cent. which has been effected in the mortality of typhoid fever. He thinks that the fundamental point in the prevention of epidemics is the strengthening of the sanitary authorities. Compulsory notification has proved one of the greatest safeguards in spite of the opposition to its enforcement.

LITTLE recommended for the prevention of typhoid epidemics: (1) universal notification, with compensation to any breadwinner prevented from following his or her occupation; (2) performance of clinical tests, such as Widals, by the local authorities, free of expense to the medical practitioner; (3) supervision of all public buildings, such as barracks, docks, railway-stations, hospitals, etc., by the local medical health-officer; (4) the water test should be insisted upon before any drains are even permitted; (5) municipal control of the water-supply with right of inspection back to the source; (6) inspection of the sources of the milk-supply; (7) all raw shell-fish should be regarded as "suspected"; (8) all cases should be treated in hospitals, under the charge of their own physicians; and last (9), typhoid excreta should not be applied to the soil.

WILLIAMS remarked that the distinct family proclivity to have the disease must not be lost sight of. In his opinion there is also a distinct race vulnerability, the Anglo-Saxon people being more prone to contract typhoid fever than the Southern races. He mentioned one town on the Mediterranean in which there are no drains, and the custom of the place is for each inhabitant to deposit his own feces outside the city wall, to be disintegrated by the elements, with the assistance of dogs, birds, and flies, and as yet typhoid fever is there almost unknown. SMITH said that the bacilli are present in the urine and feces for a considerable time after defervescence—at least two to four weeks—and that, therefore, the disinfection of these excrementitious matters ought to be continued throughout the convalescence. Burning is preferable to disinfection with strong antiseptic solutions.

In conclusion POORE said that he did not advocate the abolition of the water-closet in London, but that typhoid stools should be burnt to prevent contamination of the water; and that in the country it is best to put the excreta near the top of tilled humus. Merely digging a trench, filling it with excrement which is then covered with soil, is quite a different matter, and tends to preserve rather than to disintegrate the feces. The method advocated is by no means a new one, as it was commanded by Moses (Deut. xxiii, 13) that every one should go outside the camp to defecate, bearing with him a paddle with which lightly to cover the excrement.

SOCIETY PROCEEDINGS.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting, Held Wednesday, December 15, 1897.

THE President. CHARLES L. DANA, M.D., in the Chair.

DR. P. C. COLE read the paper of the evening, entitled

A CASE OF FEVER WITH INTERCURRENT PLEURO-PNEUMONIA. (See page 236.)

DISCUSSION.

DR. SIMON BARUCH: I have so often spoken on this subject that I can add but little to what I have already said. I would, however, like to say that the author lays too much stress upon the fact that the temperature was not reduced until several days after the compresses were first employed. The object of the compress treatment is not the reduction of temperature, which is a secondary consideration in the treatment of infectious diseases. The principal thing is to counteract the toxemia which is overpowering the patient and doing damage to the organs which maintain life. This is accomplished by the action of the compresses on the peripheral cutaneous vessels. Dr. Hutchinson of Buffalo recently read a paper in which he refers to the "skin heart"—a very important discovery, I think. He is an expert in comparative anatomy and physiology, and has traced the skin heart from its rudimentary development and goes on to show that the cutaneous vessels possess the power of contracting and dilating, and that they are supplied with ganglionic centers which control this capacity. This was clinically demonstrated by Romberg some years ago, and by others

since then. In my book it has been shown that the enfeeblement of the heart in infectious diseases is not so much due to failure of this organ—fatty degeneration—but rather to a failure of the cutaneous vessels to aid the circulation of the blood as they normally do. In the normal condition the circulation is maintained by the heart driving the blood into the vessels and capillaries, and the tone or resistance of these vessels furnishes what is known as arterial tension. This arterial tension is interfered with by the spastic contraction of the cutaneous vessels in typhoid fever and other infectious diseases. To overcome this failure of the peripheral vessels is the principal object of the cold compress. I do not use the cold bath in pneumonia because the disturbance which it involves would damage the inflamed lung and pleura. Quite a considerable reduction of temperature in pneumonia will follow even rather high temperature baths, *i.e.*, 85° F.; indeed, they often produce a greater fall than do baths at 65° F. The compress at 60° F., however, is an agent which I have found of value in stimulating the peripheral circulation, and thus enabling the heart to overcome the toxemia, although by this means the temperature is seldom reduced more than a degree or two. The compress treatment, like the Brand treatment of typhoid fever, is for the purpose of carrying the patient through the toxic period of the disease. The history of the case which Dr. Cole has narrated shows very clearly that this was accomplished. The patient did not begin to improve until the fifth or sixth day, when the natural life of the diplococcus ceased. The cold compresses maintained the patient's life until this period arrived—until the poison was eliminated. I like to dwell upon this fact because it is very generally misunderstood by the profession. Cold baths and compresses are not employed as antithermic agents. We have been taught so much about the danger of high temperature that we imagine that all that is necessary is to reduce this. If this were the case, we could accomplish the desired end by the use of antipyrin, and the result would be that the patient would be permitted to die with a normal temperature.

Dr. J. H. Fruitnight: I disclaim any criticism of Dr. Cole's diagnosis in the case under discussion, but it seems to me that it was from the commencement one of pneumonia and of a typhoid type. It is quite possible that the physical signs of pneumonia were not present on the first or second day. We observe such cases every day, especially in those in which the pathologic process begins in the center of the lung. I myself had an attack of typhoid-pneumonia which ran a somewhat similar course.

Dr. A. R. Robinson: I agree with Dr. Fruitnight and believe the case was one of central pneumonia. In regard to the application of cold compresses, I read a paper before this Society fifteen years ago in which I advocated the use of the cold pack, in the manner employed in this case, in the bronchial pneumonia of children. I do not, however, entirely agree with Dr. Baruch in regard to the object gained by cold applications. I am of the opinion that benefit is to be derived from keeping the temperature down below what is clinically regarded as dangerous; nor do I think that all the indications in this affection are met by cold compresses alone. Treatment in such an infectious disease should be directed also toward elimination, so far as possible, of the toxin which caused the dangerous conditions. Elimination is demanded and this can best be accomplished by way of the kidneys rather than through the intestinal canal. Of course, if we can cause the skin to act also in this direction, so much the better.

Dr. Robert A. Murray: The case is unusually interesting on account of the patient being an opium habitué. I have observed many of these cases, and have noticed that when they are attacked with pneumonia the disease does not frankly declare itself. I have tried to explain this by the fact that the pneumonia was a central one, but I have not always been able to believe that this was the case. The question, in these cases, also arises as to when the use of opium should be stopped. If we discontinue its use the patient is apt to die. Opium with them is a powerful support to the heart, and this is the reason why it is so hard to make them give it up. In treating these patients it is essential that the kidneys be made to act well. These patients should be given quantities of fluid so that the waste products may be washed away. It is also well to give calomel to clear out the intestines. It is a curious fact that many patients with opium-poisoning who are brought to the city hospitals develop a fatal pneumonia. This may be due to the cold effusions which are applied or to the exposure which the patients undergo. but it does seem that there is some relation between opium-poisoning and inflammation of the lungs.

In regard to cold-water applications in the treatment of pneumonia, they stimulate the patient and relieve the contraction of the capillaries, besides reducing the temperature. It is not well, however, to bring down the temperature too quickly. I have noticed that the patient makes a bad convalescence if this is done. I am a firm believer in the stimulating effect of carbonate of ammonia in these cases.

Dr. Charles L. Dana: The pneumonia of the alcoholic or opium habitué is usually a mixed infection or else one due to the streptococcus; it is rarely croupous pneumonia. The lowered vitality of the patient as well as the intensity and mixture of the infection accounts for the mortality. Infection comes sometimes through the foulness of the mouth and the stuporous condition of the patient, which allows infected matter to penetrate into the lungs and stomach. I have watched and directed many kinds of special treatment for pneumonia in the wards of Bellevue Hospital, and I have found no one method which is superior to any other. The best results have been obtained when the patient had a watchful physician and nurse who met the symptoms as they arose. Oxygen seems to have a symptomatic value. In regard to the case under discussion, I agree with Dr. Fruitnight that it was one of pneumonia in the beginning. The treatment was certainly very successful, but I would not like to say positively that the cold packs saved the man's life, for I have seen recovery in many bad cases of pneumonia without the use of these packs.

Dr. Joseph Collins: I would like to hear a general

expression of opinion of the members of this Society in regard to the use of oxygen in pneumonia. Doubtless there is an opinion abroad that the use of this gas is serviceable, but statistics are more valueless in this respect than in any other. The only way of getting at the facts is by means of personal experience. We have all employed oxygen. I have not only used it but have entirely discarded its employment in pneumonia, neurasthenia, and other diseases; for I regret to say that I have found it utterly worthless. I would like to ask Dr. Cole what his experience with this agent has been.

DR. DANA: There is no question but that oxygen produces good results symptomatically. The patient improves as he inhales it, and this is enough to justify its use. I know of only three remedies which will relieve the patient with pneumonia. One is oxygen; the second is the free use of cups, 80 or 100 being applied to the back; and the third is external applications—such as hot poultices of mustard and flour—which stimulate the circulation. In milder cases the use of stimulants like ammonia will have a good effect, and at times copious bleeding of an almost moribund patient will produce a marked improvement.

DR. L. DUNCAN BULKLEY: Twenty-five years ago, when I was a hospital interne, I had some experience with oxygen. We had an elaborate apparatus and employed it a great deal, but within six months we concluded that we had had enough of it, and its use was discontinued. The immediate results seemed to be good, but there was a disagreeable reaction afterward. In many cases we believed that this reaction was the cause of death. Since then my experience has confirmed this opinion.

DR. FRUITNIGHT: I do not think that oxygen should be discarded because it does not always save life. It gives immediate relief to a patient suffering from severe dyspnea. I have recently used it in two cases with marked benefit in each. At the Children's Hospital of St. John's Guild we have many cases of croupous pneumonia, and it always does good in those in which there is dyspnea and cyanosis. We use it there in combination with digitalis and strychnia.

DR. BARUCH: I used oxygen to a marked extent for eight or ten years, and ceased using it about six years ago. I always employ hydrotherapy in cases of pneumonia. I have the record of a case of pneumonia occurring in a girl eleven years of age, which was seen by Dr. Jacobi. The temperature was 106° F., and the pulse 160. The most powerful stimulants had been employed without effect. I stopped the use of poultices and gave her a full bath with the water at a temperature of 95° F. The temperature fell to 102° F.; she rallied, and the cyanosis, which was due to an enfeebled heart action, disappeared. She made a good recovery, though but two baths were given.

I would like to have the privilege of saying something about the remark made by Dr. Robinson to the effect that elimination is necessary in these cases and that cold compresses alone are not sufficient to meet the indications. The point in regard to elimination is a good one, but he has lost sight of the fact that baths and the wet pack aid largely in eliminating the poison. A quantity of fluid should also be given. I give my patients plenty of water to drink. I insist upon the administration of six or eight ounces of water every hour, and the same quantity of milk every other hour. It has been clinically demonstrated that the cold bath in typhoid fever increases the amount of urine. I have seen it increase to 120 ounces in the twenty-four hours in a boy of eighteen years suffering from typhoid fever, and it is often increased to sixty or eighty ounces in pneumonia. All these cases are due to infection, and, therefore, elimination should be the chief therapeutic aim. Both theory and practice show that this is accomplished by the treatment I have mentioned, *i. e.*, cold compresses, copious draughts of water, and the administration of strychnia and calomel.

DR. MURRAY: I do not think I could do without digitalis in the treatment of pneumonia. The edema of the lungs is often relieved by hypodermics of this drug. It is an exceedingly powerful agent, and is of great value when the heart is rapidly weakening. Nitroglycerin is of benefit in cases in which there is a cold, clammy perspiration; for it relieves the contraction of the capillaries and stimulates the respiratory circulation. I have been criticised for advocating blood-letting in pneumonia, but in Bellevue Hospital I have seen many lives saved by this procedure. This was accomplished by means of cups, as advised by Dr. Alonzo Clark. My experience has taught me that in pneumonia the symptoms and not the disease must be treated. In some cases I have used the cold bath with good results, and when I could not get the desired effect with this I have employed hot baths at a temperature of 108° to 110° F. Hot flannels applied to the chest are often of benefit in bringing a patient out of a condition of collapse.

DR. ROBERT H. GREENE: I agree with what has been said in condemnation of oxygen. I have employed it in a large number of cases of pneumonia, and have never seen good results follow its use, although it temporarily stimulates the circulation. The circulation afterward becomes more feeble, the month is made dry, and the pacomes more exhausted. I have used all the heart stimulants, and the one which has given me the best results is musk. The great disadvantage of this drug is that it is very expensive. Personal experience has led me to believe that there is no medicine which has a curative effect in pneumonia. I have not employed cold baths or compresses in treating this disease, but I have used cold water with good results in cases of erysipelas in which the patient was in a condition of systemic toxemia. I am inclined to think that in selected cases, if properly applied, it would be of benefit in pneumonia.

DR. COLE in closing: Dr. Baruch thinks I have laid too much stress upon the reduction of temperature in the case reported. The pack was applied on the evening of the fifth day, and the temperature did not begin to go down until the morning of the eighth day, and did not reach 101° F. until the morning of the thirteenth day.

Dr. Taylor has asked how the pack is changed with-

out disturbing the patient. This is a very simple matter. The patient is rolled over on the side, the pack is removed and a new one applied; the patient is then rolled over on the back and the compress is brought up from each side and fastened over the chest.

In regard to the diagnosis Dr. Fruitnight may be right. The case may have been one of typhoid-pneumonia in the beginning, but there was not the slightest symptom of it until the morning of the fifth day, although the patient had been seen four or five times during each previous twenty-four hours.

I employed oxygen some years ago, but cannot recall ever having obtained any benefit from its use. The after-effects are injurious. When there is cyanosis blood-letting, in my experience, is much more valuable. For years my greatest stand-by in the treatment of pneumonia has been the carbonate of ammonia. During the entire illness the bowels and kidneys should be kept open. In the case reported, in addition to the cold pack, the patient was sponged daily with cold water and then wiped dry, and was given quantities of water and milk. I agree with Dr. Robinson that this constant application of cold reduces the temperature.

More than forty years ago my sister and her husband (in command of his own vessel) were in China. My sister was attacked with pneumonia, and a surgeon from a British man-of-war was called in to attend her. After two- or three-days' attendance he was obliged to leave with his vessel, which had received orders to sail. The next day my sister's extremities, hands and feet, were cold, blue, and she was pulseless. Respiration was hurried and irregular. In desperation my brother-in-law called in a Chinese physician, none other being obtainable. This physician immediately bathed the thorax with hot water and then covered it with leeches, which were allowed to gorge themselves and drop off. My brother-in-law said he counted more than fifty. My sister recovered, and lived more than twenty-five years afterward. The Chinese physician recognized the need of blood-letting in the cyanotic stage of pneumonia, and by its prompt application undoubtedly saved my sister's life. How many of our physicians would have done the same, that is, drawn blood freely from a patient with pneumonia?

THE NEW YORK ACADEMY OF MEDICINE.—SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held January 27, 1898.

SIMON MARX, M.D., Chairman.

THE paper of the evening, entitled

MIDWIVES,

was read by HENRY J. GARRIGUES, M.D. (See page 232.)

DISCUSSION.

DR. POLK: In dealing with this question we must regard it from a high standpoint and a high plane. All the rights in the case must be taken into consideration. The people wish an educated service, and this they can obtain only through physicians, male and female. It seems to me that the duty of this Section is plain; the question is simply, Shall or shall we not have midwives? This is answered by the general feeling which exists throughout the community, in other words, there cannot be too much education; and this being the case, there is no reason why midwives should not be licensed to practise as doctors of medicine; they should be qualified in the usual way, that is, by obtaining a regular medical education.

DR. TUTTLE: I have been asked by the president of the County Society to come here to-night, though I do not understand why, as that body has not taken any action on this subject; therefore, I do not know how to represent it.

If I present my own opinion, I would say that midwives are a menace to public health and life. The women of our households should not, through ignorance, be entrusted in their hour of greatest trial to the hands of incompetent persons. It is no longer believed by any one that it is technically correct to speak of labor as a physiologic process. It is rarely so in the tenement districts of this city. I do not wish to characterize all midwives as immoral. The majority are honest, whole-souled women; but aside from all this the institution of midwives furnishes an opportunity to women of immoral character to enter the occupation of abortionist.

We, as physicians, have some rights; for instance, the right of self-preservation. This question should also be considered from our standpoint—the point of view of the physician. We should insist that the person who delivers our wives and sisters should be educated and competent.

DR. GRANDIN: My individual opinion in this matter is that the profession and the community should realize that the institution of midwives has no right to exist. I question the legality of its existence for the reason that the members of this guild are engaged in the practice of medicine. I take the ground that obstetrics is as much a part of medicine as pediatrics, and that any one wishing to practise midwifery should not be allowed to do so without passing the Regents' examination. The only thing to do in attempting to reform present conditions is to amend existing laws, thus giving midwives the right to practise or else to undertake their education—not in obstetrics alone, but in general medicine and surgery. In my opinion labor cannot be regarded as a physiologic process. Civilization has so altered woman that she is not now what she once was. During labor emergencies and complications may arise which require the judgment of an educated physician. Furthermore, the actual labor is not the only thing to be attended to; long before the advent of the expected confinement the condition of the heart, kidneys, and other organs should be under constant supervision, and such duties no midwife is competent to perform without having a regular medical education.

DR. BOLDT: I am personally in favor of abolishing the institution of midwives, but I am afraid, gentlemen, that unless an unusually strong amount of backing is brought to bear upon the Legislature, we will never be able to carry the point; and I feel we must devise some means to accomplish it gradually, if we wish to succeed at

all. My views are entirely in accord with those of the reader of the paper. I certainly favor entire abolishment.

DR. VINEBERG: I hold a different view from what has been expressed by the majority of the speakers who have preceded me. I was sent here to confer. I should like to ask what opportunity is given to teach doctors to attend midwifery cases. If some of the terrible experiences which occur in the practice of midwives are depicted, why not describe some which occur in the practice of qualified physicians. I believe in thorough education, but not in a three-years' course. Now, for example, let us take a woman in the tenement district; a midwife will talk and wait with her; a qualified physician, under the same circumstances, will apply forceps. I do not think that midwives are a curse as they now exist. It behooves us to educate and to limit them. They cannot apply forceps or sew up a perineum, and they are obliged to send for a physician if they have a difficult case.

DR. GARRIGUES: In closing, I have only a few remarks to make. Most of the gentlemen who have spoken declare themselves in favor of abolishing the institution of midwives. It should be distinctly understood that the only way to obtain what we wish is by means of a law by which we can have supervision over those who are now practising midwifery. I have not said that female physicians would be able to do all the work of the midwives. What I said was that the profession, male and female, could attend to all cases of labor. It is only in cities of large population that midwives flourish. They are not recognized by any general law. I wish to emphasize one more point in regard to the economic side of the question. I have been informed that it is not only the poor who employ midwives, but others as well. Many midwives are paid as high as $20. The general run of poor people pay the midwife $5 for her services, and I am sure that there is a number of regular practitioners who would be willing to attend labor cases for that price.

REVIEWS.

SURGICAL PATHOLOGY AND PRINCIPLES. By J. JACKSON CLARKE, M.B., F.R.C.S., Assistant Surgeon at the N. W. London and City Orthopedic Hospitals. With 194 illustrations. London: Longmans Green & Co., 1897.

THE preface informs us that this work is based upon a course of demonstrations given to students. The book is divided into two parts. The first, a general consideration of the surgical principles, and the second, a description of the pathologic processes of the special tissues and organs. The plan adopted is an admirable one. The chapter on diseases of the bone is one of the best.

Whereas the part played by bacteria is not any too strongly emphasized, the clinical features are never lost sight of, and are always harmonized with what is pathologic. Therapeutic measures receive a casual reference. The illustrations throughout are rather conventional.

As a compend of this subject, elaborately treated in other works, this book ought to appeal to the medical student.

THERAPEUTIC HINTS.

For Erysipelas.—The intense burning pain is said to be relieved and the progress of the disease favorably influenced by the use of the following application:

℞ Aristol . . . . . gr. xx
Collodii . . . . . ʒi.

M. Sig. Apply freely with a camel's-hair brush over and slightly beyond the inflamed area. This should be renewed as it scales off.

For Threadworms.—

℞ Santonin . . . . . gr. ¼
Calomel . . . . . gr. iss.

M. Ft. chart. No. I. Sig. Take one powder before breakfast every day for three days.

In addition a small quantity of the following ointment should be introduced into the rectum each night:

℞ Amyli glycerit. . . . . ʒii
Ung. hydrarg. . . . . ʒi — *m.*

An Ointment for Enlarged Glands.—

℞ Ichthyol, Ung. hydrarg., Ung. belladonnæ } aa . . . ʒi
Ung. petrolati . . . . . ʒss.

M. Ft. ung. Sig. Apply night and morning over affected glands using friction till absorbed.

For Pertussis.—

℞ Tr. Belladonnæ . . . . ʒss
Phenacetin . . . . ʒi gr. xv
Spts. frumenti . . . . ʒiv
Ext. castaneæ fl. . . . . ʒii.

M. Sig. To a child over one year of age administer ten drops every two to six hours; for a child of ten years the dose is one teaspoonful.

For Renal Colic.—

℞ Lycetol . . . . . ʒiss
Sod. bicarb. . . . . gr. xlv.

M. Ft. chart. No. VI. Sig. Take one powder night and morning in a glass of mineral water.

For Acute Laryngitis.—After a calomel purge give the following:

℞ Tr. aconiti . . . . . gtt. xii
Sod. brom. . . . . ʒii
Syr. lactucarii . . . . . ʒi
Aq. . . . . q. s. ad. ʒiii.

M. Sig. One teaspoonful every four hours.

For the Insomnia of Senile Dementia it is recommended to give from eight to sixteen grains of trional in a glass of hot milk at bedtime. A calm sleep of six to nine hours may be expected to follow the use of the drug.

For Favus.—

℞ Sulph. sublimat. . . . . ʒss
Potass. carb. . . . . ʒi
Ol. picis liq., Tinct. iodi } aa . . . . ʒiss
Adipis . . . . . ʒiii.

M. Sig. External use.

ORIGINAL ARTICLES.

THE TREATMENT OF DELIRIUM.[1]

BY JOSEPH COLLINS, M.D.,
OF NEW YORK;
PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM IN THE POST-GRADUATE MEDICAL SCHOOL; VISITING PHYSICIAN TO THE CITY HOSPITAL.

THE subject to which I ask attention is very comprehensive, and some of you may question the advisability of giving it consideration as an entity. I believe, however, that there is as much justification for discussing the treatment of delirium as there is for discussing fever, pain, headache, or constipation, which are usually considered individually, although all of them are symptoms. Moreover, although delirium is a symptom, occasionally it is the only one, or I might say the entire condition, demanding treatment.

Preliminary to a discussion of the treatment of delirium it is necessary to refer briefly to its nature and varieties.

Delirium is a general disturbance or perversion of consciousness characterized by an apparent exaltation of mental processes, which close examination, however, shows to be in reality a diminution or restriction in apperception, although association may be accelerated and in consequence seemingly enriched. It manifests itself in detail by some degree of mental irritation and confusion, by more or less transitory delusions and fleeting hallucinations, by disordered, senseless speech, and by motor unrest. It varies in intensity from the slightest so-called "flightiness," up to a most intense maniacal condition. I do not use the term delirium synonymously with insanity, although naturally admitting that the former presupposes an unsound mind during the time of its occurrence. I wish to speak principally of the temporary mental disturbance occurring with bodily diseases, and not at all of the more or less highly organized, fixed, or changeable deliria of paranoia, of chronic mania, melancholia, general paresis, and the like. In other words, in my own mind the term delirium is not given the wide application which the modern French writer accords it.

For the purpose of discussion, and in no way to be considered absolutely comprehensive, delirium may be classified into: Primary and secondary delirium.

Primary delirium, delirium acutum, delirium grave, is not a disease *sui generis*. In other words, it is not an individual affection, but a condition of varying mental disturbance, which occasionally attends different states of bodily disorder, such as collapse, intoxication, katatonia, etc., although it is often, if not always, dependent upon, or at least associated with, demonstrable changes in the cortex of the brain.

Secondary delirium is by far the more common and the less understood. It may be subdivided into the delirium of (1) infection, (2) intoxication, (3) exhaustion, (4) irritation (peripheral and central), and (5) senility.

The deliria of infection are more common in the young and in the able-bodied. They occur particularly with the diseases that are dependent upon specific organisms, such as typhoid fever, pneumonia, scarlet fever, yellow fever, puerperal fever, pyemia, etc., although delirium occurs with analogous diseases which have not yet been proven to be dependent upon specific organisms.

Deliria of intoxication may be subdivided into endogenous and exogenous. The endogenous comprise those dependent upon septic intoxicants, and are included under the head of sapremia, uremia, cholemia, diabetes, auto-intoxication, insolation, etc., while the exogenous include those due to alcohol, the drugs constituting the group of midriatics, morphin, cocain, mineral poisons, iodoform, and the like.

The deliria of exhaustion may be subdivided into those due to inanition, to acute anemia, such as results from hemorrhage, or from the presence in the blood of some powerful hemic dissociation substance, such as exalgine, the plasmodium of malignant forms of malaria, wasting diseases, excessive lactation, and the like.

The deliria of central or peripheral irritation may be subdivided into those due to local injury of the brain, such as blood clot from accidental trauma or surgical operation, to meningitis, acute encephalitis, or to other central diseases. The peripheral irritation or excitation which may be associated with delirium, is pain, a condition that could not be manifested without central interpretation. Delirium may also be due to, or associated with, states of central depression, such as those of epilepsy, hysteria, etc.

[1] Read at the meeting of the Northwestern Medical and Surgical Society of New York, January 19, 1898.

The delirium of senility requires no subdivision, for although it occurs under the apparent auspices of different exciting factors, it in reality is conditioned by the pathologic state of the vascular system incident to old age.

This classification will be found sufficiently comprehensive for practical purposes, and may afford a working basis for intelligent discussion of the subject. It may be remarked that no particular mention has been made of the delirium following surgical operations. This has been done advisedly because although such delirium is not of very infrequent occurrence, it is due to one of three things, *viz.:* to infection, intoxication, or exhaustion, and thus falls under one of the captions mentioned above.

The diagnosis of delirium is very easy, and the determination of its intensity or degree of severity depends only upon observation. But neither its diagnosis nor the determination of its severity is of any considerable service in suggesting appropriate therapy. This can only be decided upon when the causation and the pathologic associations of the delirium have been discovered. I shall very briefly take up in turn the varieties of delirium classified according to their causes as mentioned above. In discussing these varieties of delirium one has naturally an inclination to say something concerning their symptomatic individualities, and to speak of the morbid conditions which they accompany and are dependent upon. So far as possible I shall limit my remarks to their treatment, however.

The delirium of the disease which is now universally known as acute delirium, or delirium grave, resembles very much that which is associated with febrile diseases. It is ordinarily accompanied by considerable rise of temperature which has no definite course, great prostration, and by rapid development of an asthenic or typhoid state. The treatment ordinarily resolves itself into the fulfilment of two indications, *viz.:* the obtention of sleep and the maintenance of the patient's vitality. All accessory treatment should be contributory to these two ends. Without entering into a discussion concerning the virtues of the various sleep-producing measures, I trust that I shall be permitted to say that the first end in view may be more readily accomplished by the cold pack and the administration of sulphonal or trional in small doses, 10 to 20 grains, repeated every three hours, than by any other measure. When sulphonal and trional combined with the measures just enumerated fail to give the desired sleep, chloral hydrate may be given in full doses, but I never use it as the initial hypnotic in this condition unless there are some special indications. In those cases early attended by great restlessness and excitement, the cold pack is of signal service, both in conserving the patient's strength and in soothing him to a condition anticipatory of slumber. Personally, I am very adverse to the administration of drugs which produce hypnosis and coincident or subsequent depression, such as the bromids, opium, chloralamid, and hyoscyamin, although the latter is not usually rated as a hypnotic, but as a general motor sedative. Quite as important in the early stages, and much more so in the later, is the careful, judicious administration of partially or readily digested food in small quantities and of a temperature equal to that of the body. Specific enumeration of such nutriment does not seem necessary; but sufficient emphasis cannot be laid upon the fact that in reality the chances of recovery from an attack of acute delirium stand in definite relationship to the patient's capacity to retain and absorb food. Oftentimes it is necessary to indulge in forced feeding, and no time should be lost in resorting to the stomach tube. If the stomach will retain small quantities of nutriment, this method has great advantages over that of rectal feeding, no matter how carefully the latter is done. As in all acute asthenic conditions, stimulants must be given early, and this is one of the diseases in which alcohol supersedes in efficaciousness all other forms of stimulation. There should be no hesitancy in resorting to its early employment, and comparatively small experience soon teaches that more alcohol can be given with benefit in this disease than in any other form of intracranial lesion. In this, it is the exception to the rule which applies to the administration of alcoholic stimulants in diseases of the brain. Naturally, the details of treatment vary with the causative factors of the acute delirium.

Those cases of delirium which are complications or sequences of other diseases require a more varied therapy directed toward the latter. Formerly it was considered of prime importance to employ what may be called revulsive treatment, such as the administration of salines, the application of leeches to the scalp, and blisters behind the ears, but at the present day such measures are considered barbarous. The treatment may be summarized in a few words: Induce sleep, maintain nutrition, fight the progressive asthenia with stimulants, counteract the motorial unrest and fever with the cold pack, and carefully guard the period of convalescence. A good nurse is far more useful than an indifferent physician. The most important warning is: Never give motor depressants, even though apparently they are momentarily indicated. They are in reality therapeutic boomerangs. If it be borne in mind that in every case of delirium acutum, or delirium grave, we are dealing with acute parenchymatous encephalitis, we

will rarely make the mistake of administering motor depressants to overcome motorial unrest.

The treatment of the deliria which I have called secondary is a very much more important subject to the general practitioner, for they are common concomitants of the diseases which he encounters. As has already been said, delirium frequently occurs with the infectious diseases, in many of the minor forms of which it is so slight and transitory that it requires no treatment. Such are the deliria occurring in young children with measles, infection of the gastro-intestinal tract, and bronchopneumonia. In other diseases, and particularly in typhoid fever, pneumonia, and scarlet fever, its early occurrence is a danger signal which should prompt immediate action. Initial delirum is not very common in typhoid fever, nor in pneumonia. When it occurs in the former, it manifests itself either in a mild form, preceded or accompanied by a degree of anxiety which is soon followed by depression, and what is colloquilly termed "flightiness." Such a mental state has absolutely no relationship to the temperature, and may even precede the occurrence of the latter. In other cases, the delirium is so severe as to constitute actual mania. These cases are likewise infrequently attended with high temperatures. They differ very materially both in their clinical manifestations and in their indications for treatment from the delirium which occurs during the third and fourth weeks of the disease. The former variety stands in direct relationship to the amount and intensity of infection, while the latter is frequently, but not always, an exhaustion delirium. The treatment of initial delirium of typhoid fever should be directed particularly to counteracting the effects of the infection on the nervous system, and, personally, I am convinced that no form of therapy meets the requirements so efficaciously as the administration of one or two large doses of calomel, followed by the injection of a large amount of saline solution into the intestines, or subcutaneously beneath the mammary gland. In two cases of typhoid fever with initial delirium, both of the acute maniacal form, the adoption of high rectal injections of warm saline solution was followed by most gratifying results, and had not such been the case I should not have had the lightest hesitation in using it subcutaneously. Its presence in the blood seems to have a beneficial influence in neutralizing or counteracting the pernicious action of the poisonous matters on the vital centers. The treatment of delirium occurring in the later stages of typhoid fever does not differ materially from the treatment of delirium due to other exhausting conditions.

In this connection I desire to say a few words concerning the relationship of fever to the occurrence of delirium, not alone in typhoid fever, but in other febrile diseases. There is a well-defined conviction in the minds of many physicians that the occurrence of delirium stands in definite relationship to the degree of febrility. Personally, I do not share this opinion, and am inclined to the view that fever *per se* plays absolutely no part in the genesis of delirium, and consequently that treatment directed immediately to the fever is of no avail in counteracting the delirium, except in so far as such treatment is operative against the factors upon which the delirum is dependent. I anticipate that this attitude may not receive the endorsement of those who advocate the most rational and most efficacious plan of treating infectious disease to-day, the plan which we may for brevity's sake call the hydric method.

If hyperthermia is in itself sufficient to cause delirium, this symptom should be a concomitant of hyperthermia artificially produced, and a common symptom of disease attended by high temperature. A few minutes' retrospection on the part of any one of us will, I believe, show that this is not a fact. For instance, witness the colossal rise of temperature which sometimes occurs in malarial infection, in rheumatism, and occasionally even in insolation, while the mental facilities remain unimpaired. On the contrary, the antithesis of delirium is quite as frequently the mental state in such cases. It cannot be legitimately said that because the application of cold water, according to the most approved plan, in the acute febrile diseases has a salutary action in preventing delirium and in controlling it when it does occur, that the hydric procedure prevents or overcomes the delirium by lowering the temperature. On the contrary, the cold water acts by facilitating the elimination of the poisons in the blood which are acting deleteriously upon the anterior poles of the cerebral hemisphere; it assists the blood to oxidize and consume these injurious products, and it stimulates the vital centers to renewed effort in their combat with the overwhelming agencies which are manifesting their peccant activities by enshrouding the sensorium. True it is that the hydric measures simultaneously reduce the temperature, and their beneficial effects on these two symptoms may be coincident, but this in no way should foster the belief that the two are interdependent. On the contrary, it seems to me that fever is conditioned by a mechanism quite apart from that which conditions delirium, and that to speak of febrile delirium to cover the deliria of infectious diseases is an unwarrantable assumption of the interdependency of these two symptoms.

Initial delirium in the pneumonia of the adult al-

ways means one of two things: the occurrence of the disease in an alcoholic subject, or an extremely severe infection. Occurring in the infant it suggests that we have to do not only with a severe infection but with an apical involvement as well. If alcoholism, or, better said, the alcoholic habit, can be excluded, the chances are that the patient has a streptococcus pneumonia, and not a diplococcus or tuberculous pneumonia, as initial delirium is of much more common occurrence in the former variety. As an indication for the election of therapy, it matters not very much upon what the delirium is dependent, as the treatment in every instance may be summarized in one word: stimulation, unless, indeed, the administration of a specific antitoxin be considered. The election of the stimulant, or combination of stimulants, may vary. If the patient be alcoholic, it will be necessary to continue administering to him the prop that served him so ill in times when he could make his own selection, and to combine it with strychnin; while in non-alcoholic cases the more diffusible stimulants and digitalis may be indicated. Here again it is necessary to say a word regarding the selection of a hypnotic. In children, and in non-alcoholic adults, chloral in small doses is the best hypnotic, especially in the beginning of the disease. At least, this has been my individual experience. For the insomnia and delirium occurring later in the course of the affection, and in alcoholics, sulphonal has served me more satisfactorily, possibly because it is always given in hot milk, which of itself is not inconsequential as a stimulant and sedative.

The deliria attending scarlet fever, and, in fact, I may say all of the eruptive diseases, are best counteracted in the early stages by the application of the ice cap and the cold pack. On account of the frequency of renal complications, and the widespread belief on the part of the laity that cold water makes the eruption "strike in," there is often great objection by parents when the cold pack is suggested, but I am sure that no other measure or combination of measures compares in efficaciousness with it in the treatment of this symptom, even though it is not associated with hyperthermia.

The delirium attending the severer infections, such as puerperal fever and pyemia, requires practically the same treatment as that accompanying septic pneumonia. In all of these, as in delirium acutum, sleep must be obtained at all hazards, and the prop of the patient's vitality, *viz.:* his nutrition, must be constantly bolstered. Here the mistake of giving motor-depressants, such as the bromids, chloral, and hyoscyamin, should, I believe, never be made. It should also be said that it matters not how maniacal the patient may become, mechanical restraint should not be employed except as a last resort. All mechanical restraint, with the exception of that which makes captive the legs alone impedes respiratory freedom, and thus becomes a very powerful influence in contributing to asthenic consolidation of the lungs. The restraining influence of one or more nurses, combined with the sleep-producing potency of 20 grains of sulphonal or trional, administered in hot milk or in some form of alcohol, is far more efficacious.

Passing now to a consideration of the deliria of intoxication, I shall say very little concerning the endogenous varieties, as the treatment here consists of efforts to overcome the source of the *materies morbi*, to counteract its effect upon the central nervous system, and to secure its elimination from the system. I have no faith in my ability to say anything that would interest or be worthy of attention concerning the treatment of sapremia, uremia, cholemia, diabetes, etc., and shall content myself in allowing these to pass without more direct attention than is contained in the general treatment of delirium. I may say parenthetically, however, that if two important facts be kept in mind concerning the toxic and autotoxic deliria the treatment will be very much simplified. These are: Nature should be assisted to get rid of at least some of the poison in the system, then strike at the source of the intoxication. If the latter be a wound that is filled with iodoform the removal of the latter is a very evident duty, but if the absorbent surface be the entire gastro-intestinal tract, and the *materies morbi*, the as yet unknown toxin which produces the clinical phenomena of insolation, the task is much more difficult. But, as will be said later, after all, the important matter first of all is to determine the pathologic association of the delirium.

In the treatment of deliria of exogenous origin I have had a considerable experience, and consequently some facts have been impressed upon me. Of the deliria having their origin in toxic substances coming from without, delirium tremens is the most important, because it is so frequently encountered and because it is so uniformly fatal after the first or second attack. All toxic deliria are associated with more or less profound asthenia, and the first aim of treatment should be the counteraction of this asthenia while simultaneously fulfilling a more pointed indication. In alcoholic subjects there has almost invariably been a prolonged and outrageous indulgence in substances which destroy the metabolic functions of the economy, and before measures can be taken to counteract the influence of the poison itself upon the nervous system the *prima via*, and the

avenues leading up to it, must be carefully attended to. Therefore, of paramount importance and antedating all other therapeutic indulgence is the introduction of small quantities of partially digested or predigested nourishment into the patient's alimentary tract. There should be no hesitation in resorting to uncommon avenues of introducing nourishment if the patient, because of anorexia, or under the dominancy of a delusion or hallucination, refuses food. I am so convinced that at least one-half of the patients in the early stages of delirium tremens would weather as satisfactorily the danger incident to their vice by this plan of treatment alone that I not infrequently employ it to the exclusion of all other treatment save that of some of the rapidly acting hypnotics which are not depressants. To cite one illustration: The last case of delirium tremens which I observed was in a man who is as yet under observation, and who came to me with a record of having consumed upward of a quart of whisky every day for seven previous months, in addition to from four to six grains of morphin, taken hypodermically. His mental and physical conditions mirrored the typical description of *mania a potu*, with a well-pronounced typhoid state. He received no other treatment than attention to his nutrition, such as suggested above, careful nursing, the use of the warm pack twice daily, and repeated doses of trional in small quantities, taken in hot milk. He made a good recovery, and at the end of a fortnight, being well advanced in the convalescent stage, the administration of strychnin in $\frac{1}{30}$-grain doses three times daily was begun.

I know how extremely common it is for physicians, when they find themselves face to face for the first time with a patient suffering from delirium tremens, to write a prescription containing about 15 grains of chloral, 30 of bromid, and from 3 to 6 drops of tincture of digitalis, and instruct that this be administered every four hours, and at the same time give more or less perfunctory instructions regarding the diet. At a subsequent visit, if the patient is very delirious and difficult to restrain, they give a hypodermic injection of morphin, and possibly leave orders that it be repeated, if necessary. Candor compels me to state that I have never been able to convince myself that such a combination does not very frequently, by adding to the patients asthenia and to the depravity of the blood, do more harm than good, and I confess that I should have to be pushed very hard before indulging in the administration of a mixture recommended in one of the most recent treatises on therapeutics. The writer of the article to which I allude says that it is his custom to give dram doses of the bromid of ammonium, 15 grains of chloral, and $\frac{1}{4}$ grain of morphin, in order to induce sleep. Such a mixture, it seems to me, has entirely too high a potentiality of dangerousness to give to any person, but particularly to one whose vitality is at a low ebb. As a matter of fact, I never use the bromid and chloral mixture, nor hyoscyamus, until four other hypnotics have failed me, the four being sulphonal, trional, paraldehyd, and chloralamid. If the stimulants, strychnin and digitalis, are properly used, and if the indications for maintaining the patient's strength as mentioned above are fulfilled, the depressant drugs will rarely be found necessary.

I am not inclined to the use of alcoholic stimulants in the treatment of delirium tremens, unless this condition is associated with pneumonia, as, unfortunately, it not infrequently is. When indications of this complication show themselves, whisky and brandy freely given will sometimes save the patient's life.

The delirium of exhaustion is the one which is the least frequently interpreted of all the deliria. It seems difficult for some to admit the reality of its occurrence, but although it is one of the rare forms, there can be no doubt of its existence. Its association suggests the indications for treatment, and there would be no difficulty in following out the proper therapeutic plan were it not that its recognition must grow out of a process of exclusion. The treatment is symptomatic, and should be directed particularly to overcoming exhaustion.

Senile delirium is in reality a delirium of exhaustion, remotely conditioned by pathologic changes of the blood-vessels, and immediately by disordered intracranial blood-supply. Its chief clinical characteristics are that it is of the so-called "busy," active kind, and it almost invariably occurs at night. During the day the patient may have customary mental lucidity. In addition to the ordinary measures to maintain the patient's nutrition, special precautions should be taken to prevent deleterious lowering of vitality in the early morning hours. If such a patient is taking one of the iodin salts and nitroglycerin, it is very advisable to give him a full dose on retiring, and also a liberal amount of warm peptonized milk and to repeat this once or twice during the night, even though it be necessary to awaken the patient. Alcoholic stimulants are likewise of signal service in preventing delirium of this nature. Their efficaciousness seems to be increased if administered in hot water or in hot milk. The value of dry heat to the extremities should not be overlooked.

The deliria of central or peripheral irritation is a very large subject. and one that I cannot attempt to handle in a brief consideration of this kind. From the slight experience which I have had with cerebral injuries, either accidental or surgical, I am

inclined to the opinion that surgeons are more apt to seek the cause of the delirium in infection than they are in local irritation. There may be ample reasons for this, but nevertheless delirium is so frequently a symptom of meningeal and cerebral irritation, unattended with any considerable infection or intoxication, that its occurrence should cause no astonishment. When the irritation is of a post-traumatic origin, and the delirium is continuous, this should be sufficient justification to warrant operative interference.

The delirium associated with states of central depression, such as epilepsy and hysteria, demand the greatest circumspection in their diagnosis and interpretation. Psychic epilepsy, that is epilepsy in which the customary motor explosion, let us say, is replaced by psychic phenomena of an uncontrollable nature, is, proportionately to the ordinary epilepsy, rather uncommon; and this, perhaps, accounts for its lack of recognition when it does occur. The psychic equivalent may assume the form of delirium, even from the very beginning, or an epilepsy starting in as an ordinary motor-epilepsy may alternate in its explosions, one attack being externalized by a convulsion, another by a delirious state. The same is true of hysteria, although hysteric delirium is relatively more common than epileptic delirium. In this connection it may be well to say a word of the delirium which occasionally accompanies chorea, constituting chorea insaniens. Occasionally there is superadded to the typical symptoms of a severe Sydenham's chorea, a profound state of unsystematized delirium. It has been suggested by some writers that the delirium is the expression of an extensive encephalitis, it being known that in some cases of chorea which have proved fatal, vascular changes pointing to a mild degree of parenchymatous inflammation have been found. Personally, I am not inclined to this view. I believe that the delirium from which chorea insaniens takes its descriptive adjective is analogous and comparable to the delirium which is occasionally an accompaniment of rheumatism, and that its causation is to be sought for in the profound dissociation of the component parts of the blood occurring in both of these diseases.

The treatment of chorea insaniens would be very simple were it not for the profound vascular depravity behind the chorea, for this militates against the administration of a drug, exalgin, which if given in 3- to 5-grain doses and repeated every two or three hours, would soon stop the delirium, at least temporarily; but as exalgin tends to liberate the hemoglobin and thus act as a severe hemolytic, it should never be used. The general treatment of asthenic delirium, enforced rest in bed and the administration of small doses of bromid, suffices to control the attacks in most cases. This is one of the forms of deliria in which hyoscyamus should never be given.

The treatment of epileptic delirium is practically the treatment of status epilepticus, save that the necessity for giving stimulants, which is so patent in the latter condition, is not so urgent. In reality, the treatment is small doses of one of the bromid salts; let us say, 10 grains every hour or two, which with mechanical restraint, usually suffices to terminate an attack. The treatment of hysteric delirium oftentimes baffles every resource of the physician, and then after resisting them all, disappears spontaneously. The most potent element in its treatment is complete isolation and the application of cold packs, although in many of these cases the salts of hyoscyamin given in doses up to their full physiologic limit are of the greatest benefit.

General Remarks on the Treatment of Delirium.—After thus wandering over a very large subject, and touching here and there some of the more important points, I should like to ask indulgence for a few general remarks on the treatment of delirium, fully cognizant that therapeusis must vary in every case, and that the indications in one kind of delirium may not suffice or be sufficient in another. Nevertheless, there are a few underlying principles in the treatment of all deliria, and it is these which I shall here endeavor to lay down, prefacing my remarks by saying that, in the opinion of the writer, sedatives are used too frequently and too indiscriminatingly. Bromids, especially, are frequently given offhand, in large doses, and over quite an extended period, apparently forgetful of the fact that they may, by adding to the vascular depravity which is so often at the bottom of the delirium accompanying asthenic states, intensify and prolong the duration of the symptoms for which they are given.

The general indications in the treatment of delirium are first to secure sleep; second, to overcome motor unrest; third, to prop up and maintain the patient's vitality by contributing to his nutrition, and fourth, to discover and remove the cause upon which the delirium is dependent.

To meet the first indication hypnotics are almost always required, although it should never for a moment be forgotten that an hour's sleep induced by measures taken to fulfil the third condition is far more salutary than three-hours' sleep obtained by the use of a hypnotic. Moreover, that in many forms of asthenic delirium, whether the asthenia be induced by infection, intoxication, exhaustion, senility, or what not, sleep is more readily induced and maintained by measures directed immediately against the asthenia than against the insomnia. In the

selection of a hypnotic the one least depressant to the patient's vitality and least apt to be followed by depression should always be given preference. The motor depressants should never be used in the delirium accompanying the asthenic state, except as the very last resort. In certain forms of sthenic delirium, and especially those in which a sedative effect cannot be produced by the external application of water, drugs which are motor depressants and at the same time hypnotics may be used with the greatest benefit. Of these, the alkaloids of hyoscyamus are the most available.

The second principle is that great care should be exercised in the application of mechanical restrain in all forms of asthenic delirium, lest the encroachment on respiratory capacity lead to pulmonary complications which jeopardize the life of the patient. Whenever possible, physical restraint is very much less dangerous.

Concerning the third principle, that of maintaining the patient's vitality, I have perhaps already said sufficient.

The meeting of the fourth indication, *viz.:* the discovery and removal of the cause of the delirium, is after all the most essential procedure in the treatment of this symptom. To do this the pathologic association must be determined, and then our ammunition leveled directly against it, while simultaneously the three first enumerated principles are guiding us in symptomatic therapy.

PNEUMOTOMY.

BY DUDLEY TAIT, M.D.,
AND
ALBERT ABRAMS, M.D.,
OF SAN FRANCISCO.

AFTER the invasion and conquest of the abdomen and head, surgeons have in recent years turned their attention to the numerous diseases of the chest which have baffled medical treatment. Although pneumotomy is mentioned as early as 1710 by Baglivus and advised by Börhave, Pouteau, and, others, it is quite evident that the operation was undertaken unknowingly, in the rare cases in which the lesions resembled empyema or abscess of the chest-wall. Hence, as Terrier justly remarks in his masterly "Lessons on the Surgery of the Pleura and Lung," the caption pulmonary surgery should be reserved for those cases in which the chest-wall and pleura are deliberately traversed with the intention of attacking an intrapulmonary lesion." Truc's valuable monograph (1885) was the first important contribution to this subject. In 1894, Fabricans of Cracow tabulated all the cases in the literature of the previous twenty years, amounting to thirty-one cases of pneumotomy for abscess, and twenty-six for gangrene. The following year, with Reclus' admirable address before the French Surgical Congress, and the extensive discussions which followed it, the question assumed both a scientific and practical aspect. Of late, French surgeons have done much, by careful clinical, physiologic, and experimental investigation, to widen the heretofore very narrow limits of pulmonary surgery; and already many surgeons of prominence believe this branch of the art is near its greatest height, if only the indications promising complete success be counted (Paget, Kochler). When, however, we consider Delagéniere's audacious exploratory pleurotomy, which he places on the same footing as laparotomy and trepanation for exploratory purposes, we cannot refrain from suggesting that the limitations of pulmonary surgery are as yet undefined.

The great obstacle to progress in this direction is the absence of precision in pulmonary localization, and regarding this, it is to be hoped that surgeons will utilize the results obtained by Bouchard by means of the X-rays, which may justly be considered as valuable in the examination of the chest as in the diagnosis of bone lesions. We regard the illumination of the chest as of great diagnostic value in the detection of patches of consolidation which, in consequence of their diminished area or depth from the chest-wall, elude the results of percussion and auscultation.

The following case of pneumotomy is reported on account of several interesting clinical features, and also as partly illustrative of some of Delagéniere's suggestions in regard to the exploration and drainage of pulmonary lesions:

J. M., aged seven years, weight forty-four pounds. There was no history of tuberculosis in the family. Three weeks before, according to the statement of the attending physicians, the patient contracted croupous pneumonia, primarily involving the lower lobe of the right lung, and, subsequently, the lower and part of the upper lobe of the left lung. The pneumonia in the right lung underwent resolution, but the areas of consolidation in the upper portion of the lower lobe of the left lung persisted. The symptoms presented—night-sweats, fever, rapid and progressive emaciation, and occasional slight chills—were suggestive of an acute suppurative process involving the lung; temperature, 104° F.; pulse, 140; respiration, 24.

The first exploratory puncture, at the lowest portion of the area of dulness in the mid-axillary line, proved unsatisfactory; the second, at a higher and deeper point, revealed the presence of thick pus. The needle did not oscillate with the movements of respiration; which fact led us to affirm the presence of pleural adhesions directly over the affected portion of the lung. Pneumotomy was performed two

hours later through a U-shaped incision of the skin and muscles. Nine cm. (3½ inches) of the seventh and eighth ribs, between the anterior axillary and scapular lines, were resected. The pleura was opened after a fruitless attempt at extrapleural palpation by Tuffier's method. With the use of retractors the entire region could be explored with the greatest ease and satisfaction. The only adhesions present were about 7 cm. (2¾ inches) above the opening. Inspection and *manual* exploration showed the lung to be free below the adhesions and markedly hepatized. There was no effusion in the costodiaphragmatic cul-de-sac. After shutting off the pleural cavity with gauze, the lung was incised to the depth of 3 cm. (1¼ inches), with the Paquelin cautery, heated to a dark-red color. About 75 c. c. (2½ oz.) of thick, non-fetid pus immediately escaped. The pulmonary opening was then increased, and the cavity found to extend upward toward the surface of the pleura. Its walls were covered with sphacelated tissue, but did not seem thickened. After breaking up a number of trabeculæ, and searching in vain for secondary purulent collections, the cavity was thoroughly swabbed and gently packed with gauze. The gauze in the pleural cavity was then removed, and the skin and muscle flap sutured. At no time during the operation was there any trouble from hemorrhage. Cultures were made from the pus, but, owing to an accident in the laboratory, the result remained doubtful.

After the operation there was an immediate improvement in the temperature, which fell 3° F.; the pulse and respiration were only slightly modified. Patient ceased to lose weight. Excepting the slow elimination of the sphacelated walls and the consequent tardy appearance of healthy granulations, the wound offered nothing of interest. Four weeks after the operation friction sounds could still be heard at the point already mentioned. One month later the wound had entirely closed, and nothing in or over either lung could be elicited by physical examination. Skiagraphy then revealed opacity at the base of the left lung, probably due to cicatrical tissue. The mobility of the lung border at this point was absent. The lower border of the lung on this side was 2 cm. (¾ of an inch) higher than the corresponding border of the right lung.

Although the exploring needle revealed the seat and nature of the pulmonary lesion, it was, nevertheless, misleading in regard to the pleural adhesions. The absence of oscillations may not, therefore, always indicate the existence of adhesions, a fact already mentioned by Quincke, Rochard, and Terrier. In the diagnosis of abscess of the lung, the results furnished by the exploring needle are frequently as unreliable as in other regions; the pus may be present and not escape through the needle, or the cavity may be nearly or entirely empty after an attack of coughing. On the other hand, the use of the needle is not devoid of danger; death from pneumothorax in a case of emphysema has been reported by Fränkel, and purulent pleurisy is mentioned as a complication by Israel, Pochat, and Winge. Exploratory puncture should, therefore, constitute the first step of the operation, serving as a guide to the seat of the intrapulmonary lesion.

It will be noticed that after finding the adhesions above the pleural opening it was, nevertheless, not considered proper to make a new incision and thus transfer the field of operation to a higher level immediately over the adhesions, as in a successful case reported by Bazy. If a similar plan had been adopted in the present case the object of the operation would not have been attained. The reasons for preferring the direct low pulmonary incision were: (1) the results of the exploratory puncture; (2) the desire to secure the best possible drainage, an indispensable element, as Delagéniere has so clearly demonstrated. Moreover, it was inferred that if the abscess extended to a point in the vicinity of the pleural adhesions it could be easily laid open by extending the pulmonary incision directly upward by means of the cautery.

Too much stress cannot be laid upon the facility afforded by a liberal resection of the ribs in all cases of exploration of the lungs. De Cerenville, Truc, Lauenstein, and many others have insisted upon this and have shown that the gravity of the operation is thereby diminished, and, in purulent intrapulmonary lesions, the retraction of the cavity and apposition of its walls greatly favored. This is especially true in abscesses of long standing, for in such cases the process of repair is notably influenced by an extensive sclerotic zone, chronic bronchitis, and dilatation. Simple resection of one or two ribs may then prove inadequate, and thoracoplasty by Schede's method becomes necessary. Cases of respiratory trouble attributed to extensive resection of ribs have been reported by various surgeons; but it is quite improbable that the accidents were caused by the procedure, for very much more extensive operations on the chest-wall have since been made without being followed by similar accidents (Terrier). Spinal deviation (Ollier) has likewise been mentioned as a sequel.

The stripping of the parietal pleura off from the ribs in Tuffier's method of extrapleural explorations is not as easily accomplished as may be imagined; it requires considerable practice on the cadaver. Terrier states that he saw Tuffier himself tear the pleura, but that no symptoms suggesting pneumothorax ensued. Lejars and Brun each report a failure with this method. Surgeons differ greatly regarding the extent of the pleural incision in pleural and pulmonary explorations. Bazy prefers a small opening sufficient to permit digital exploration; Delangéniere, in three successful cases, made a liberal

opening through which the entire hand could be introduced. Terrier inclines toward the latter method. Truc holds that absence of adhesions over the pulmonary abscess constitutes an absolute indication against operation. This rule, although supported by some eminent surgeons (Quincke, Volkmann), is questionable, and happily passing into oblivion. Terrier justly remarks: "In either case one should unhesitatingly continue the operation and not be influenced by a condition of such meager interest." In the majority of cases the preliminary use of caustics (Quincke), iodoform gauze (Neuber), or needles (De Cerenville), in view of creating adhesions, may be condemned for very much the same reasons as all stomach and gall-bladder operations performed in two stages. Many surgeons advise suturing the two layers of pleura around the seat of operation before incising the lung (Godlee, Roun), but such a procedure must necessarily be restricted to a group of well localized, circumscribed lesions (gangrene and apical cavities especially). In the present case, it was thought wiser to first shut off the pleural cavity with gauze and explore the lung before suturing.

The avoidance of pneumothorax has greatly occupied all those interested in pulmonary surgery, and, although many expedients have been proposed, the question still awaits a practical solution. Quénu advises tracheotomy in cases of large opening of the pleural cavity; Delorme considers this procedure unjustifiable, and resorts to cocain anesthesia or incomplete choloform narcosis. Tuffier and Hallion, in a series of interesting and precise experiments, have demonstrated that a slight increase in the intrabronchial pressure does not interfere with the pulmonary or general circulation. Tuffier, therefore, rejects tracheotomy, which, in his opinion, is as dangerous as pneumotomy, and seeks to neutralize the retractility of the lung with laryngo-tracheal insufflations by means of a special laryngeal tube. Experience alone will determine the value of this ingenious method. More audacious than others, Delangéniere, the clever surgeon of Mans, does not anticipate much danger from pneumothorax, and in his exploratory pleurotomy, after resecting the eighth, ninth, and tenth ribs, he opens the pleura sufficiently to admit the entire hand; the lung is seized with forceps and secured to the parietal pleura. In considering this bold but nevertheless successful procedure, it becomes quite evident that operative pneumothorax is not as dangerous as heretofore believed. In the course of nephrectomy, the pleura has been accidentally incised, and a similar accident occurred while removing a hydatid cyst involving the convex surface of the liver. No alarming symptoms developed in either instance. In the present case the cautery, heated to a dark-red color, was used for incising the lung on account of the marked hyperemic condition. According to Terrier, the knife should be reserved for those cases of dense sclerosed tissue in which hemorrhage is not feared.

Whilst the possibility of recovery without operation is admitted in certain cases of abscess of the lung, either by absorption or by discharge into the air-passages, the fact, nevertheless, remains that basic cavities are frequently ill-drained through the bronchial passages; septic absorption is a common occurrence, and sudden suffocation due to rupture into a bronchus is not rare. Furthermore, in large cavities of the apical region, in spite of bronchial evacuation, the process of repair is greatly hindered and somestimes rendered impossible by the rigidity of the thoracic walls. In the present case, the septic condition constituted the primary indication for operation, and, judging from the absence of cough, the extensive sphacelated walls, and surrounding congested area, it may be safely said that nothing short of surgical interference would have been of the slightest value. As Reclus remarks, "Wherever there is an abscess there ought to be an operation; no need to wait for fever, septic absorption, and the resulting alarming condition. Delay is unjustifiable, save perhaps in very small abscesses draining easily and rapidly into the air-passages or in multiple abscesses requiring for their evacuation unwarrantable mangling of the chest. Fortunately, these latter cases are exceptional." Even if the intrapulmonary exploration proves negative in certain purulent lesions, the operation may, nevertheless, do good, for in numerous cases it has been noticed that the cavity subsequently ulcerated and broke through its wall at this point of least resistance. (Quincke, Reclus,and Groube.) As illustrative of this point, and also of the difficulties experienced in localizing lesions of the middle and lower part of the lungs, in spite of direct exploration, and, furthermore, as an example of the tolerance of the lung to traumatism, we recall a case under the care of a surgeon of this city, at the French Hospital, in 1893.

A man, aged forty years, contracted severe bronchitis a year previously, and at the time of admittance to the hospital expectorated large quantities of very fetid pus every morning. No tubercle bacilli were present. Physical examination pointed to a cavity in the lower portion of the right lung, with corresponding dry pleurisy. Ten cm. (4 inches) of the eighth and ninth ribs were resected in the axillary line, the pleura incised and found adherent. The Paquelin cautery was then sunk into the sclerosed lung to a depth of 2 to 3 cm. (about one inch) at two distinct points. Only a little air and mucus

escaped. The wound was packed with gauze. The patient showed immediate signs of improvement, and within two months entirely recovered from the pulmonary trouble.

In the drainage of pulmonary lesions tubes should be used with circumspection; if allowed to remain long hemorrhage from ulceration of the blood-vessels may result, as illustrated in the cases reported by Walsham, Grainger Stewart, and Sutherland. Gauze, with or without a tube, is certainly to be preferred. Cases proving the great dangers resulting from irrigation in pulmonary surgery are quite numerous, and we firmly believe the same verdict holds equally good in surgery of the pleura.

SOME MANIFESTATIONS OF SYPHILIS IN THE UPPER RESPIRATORY TRACT, WITH REPORT OF A CASE OF CHANCRE OF THE NASAL SEPTUM.[1]

BY JOSEPH A. KENEFICK, M.D.,
OF NEW YORK;
ASSISTANT SURGEON IN THE THROAT DEPARTMENT OF THE MANHATTAN EYE, EAR, AND THROAT HOSPITAL; AURAL ASSISTANT SURGEON NEW YORK EYE AND EAR INFIRMARY.

IT is a most important fact to be borne in mind by every physician and surgeon that in the nose and throat are constantly found all the different lesions of syphilis, and at all periods of life, from the snuffling infant, with hereditary taint, to the external and internal deformities of the advanced disease. As eminent a physician as Professor Osler of Baltimore only recently made the significant statement before the New York Academy of Medicine that he had said to his students: "the only disease one must know thoroughly is syphilis; if one knew syphilis, one knew internal medicine."

While the usual genital lesion may attract but passing attention, and the characteristic cutaneous manifestations entirely escape detection, the comparatively insignificant nose or throat affection for which the patient seeks relief may be the first intimation of the true condition. This outlines an occurrence which is by no means infrequent; indeed, it is so common that my own experence in dispensary work has led me to determine the presence or absence of specific disease as almost the first step in diagnosis.

The diagnosis of syphilis in the nose is comparatively easy. The "snuffles" of the infant with inherited disease is quite characteristic, but by no means pathognomonic. Not all infants presenting this symptom are syphilitic, especially after the earlier months. Careful examination in this class of cases may disclose the presence of a foreign body or a diphtheritic membrane in the nasal chambers.

During last summer I observed a child at the Manhattan Eye and Ear Infirmary (Dr. Knight's clinic) who had snuffles. There was a brown sanious discharge from both nostrils, and a significant excoriation of the upper lip beneath the right meatus. Relief for this condition, which the mother called "chronic catarrh," had been sought in vain at various hospitals and dispensaries. A foreign body was found in the right nostril, which on removal proved to be a long piece of stout linen cord that had been introduced into the nose six months before. Complete relief promptly followed removal of the foreign body. It was evident from the history that the antisyphilitic treatment by inunction had been experimentally tried. On the following day another child was observed, who, to all outward appearances, presented the same condition and symptoms; and yet examination showed the presence of a diphtheritic membrane on the septum and inferior turbinate bone of the side most affected, and the Health Department reported that the case was one of true diphtheria.

Primary syphilis of the nose is not a very rare condition. Up to 1894 thirty-seven cases had been recorded, constituting between three and four per cent. of all cases of extragenital infection. In such cases the virus is undoubtedly introduced by means of the finger, and the chancre is nearly always situated on the septum, occasionally on the turbinate, and just within the nasal orifice. Characteristic mucous plaques are also found in the nose, though they rarely appear on the septum. When a secondary syphilis is observed, without evidence of initial lesion, but with a history of persistent obstructive rhinitis, one ought always to think of the nose as a possible seat of primary infection. Through the courtesy of Dr. C. H. Knight I am able to give the history of the following case, which was observed in his clinic at the New York Post-Graduate Hospital.

Marie W., German, aged thirty years, the mother of two healthy children, and whose husband, as far as she knew, was also healthy, had always been well up to three months before presenting herself for treatment. At this time she began to suffer from persistent stenosis of the left nostril, with pain and occasional slight bleeding. The affection had continued in spite of all sorts of local treatment.

Examination revealed a shelving ecchondrosis of the septum, a characteristic punched-out ulceration, with well-defined border—rounded and elevated, and a dirty, yellowish base. Marked hypertrophy of the inferior turbinate occluded the nostril. On lips, gums, soft palate, and right faucial pillar, were characteristic mucous patches. The usual adenitis was present, the submaxillary gland on the affected side being especially prominent and painful.

[1] Read at a meeting of the Harvard Medical Society of New York, December 18, 1897.

The patient had noticed great loss of hair during the previous two weeks. The case was diagnosed by Dr. Knight as one of chancre of the septum. Under specific treatment continued ten days the ulceration promptly healed, with marked improvement in the general and local conditions.

Between secondary and tertiary manifestations in the nose Dr. Hajek of Vienna recognizes certain difficulties of classification. He claims that an early periosteitis and chrondritis resulting in quick destruction of bone may sometimes occur, and that infiltrative gummatous syphilis may be observed as early as the sixth month of the disease. Erythema of the mucous membrane is the usual nasal accompaniment of secondary syphilis.

Tertiary syphilis of the nose, according to the usual classification, is observed only too often. The early treatment in these cases is always an interesting question, and one in which it is difficult to determine facts. My own impression is that with an early diagnosis and proper treatment, continued over a sufficient length of time, there should be practically no tertiary manifestations. When such occur they appear in the form of gummatous tumors or as a necrotic process most frequently involving the bony and cartilaginous septum, at first continuing quietly beneath the intact mucous membrane and later breaking down with great proliferation of granulation tissue. Finally, the process becomes purulent and the sequestri find their way out or remain until removed by a surgical procedure. Ultimately there is left a general nasal atrophy, accompanied by various external and internal deformities.

The diagnosis of nasal syphilis should be made from the history of the patient, the microscopic character of the new tissue, and from the result of specific treatment.

I have now under observation a woman who presented herself for treatment on account of nasal stenosis. A granular tumor growing from the septum had completely occluded both nostrils. There was no history or evidence of infection or dyscrasia of any sort. The pathologist reported that the specimen presented all the features of syphilitic granuloma. The growth is at present disappearing under the administration of syrup of hydriodic acid.

The history, gross and microscopic appearances of new growths in this region may be so misleading that general surgical measures should be resorted to only after great care and deliberation. A pathologist's "small, round-cell sarcoma" recurring after complete extirpation through the superior maxilla at the hands of the general surgeon, and melting away again under generous doses of potassium iodid is by no means an impossible occurrence.

The nasopharynx of young subjects not infrequently furnishes evidence of hereditary syphilis, taking on the form of obstruction and stenosis due to contraction of the soft parts from the presence of cicatricial tissue. Of primary syphilis in this region —the nasopharynx, the less said the better. Doubtless all have heard of that famous Eustachian catheter in Paris, which some years ago was discovered by Fournier, but not before it had contributed forty such cases to the literature.

Primary lesions of the lips and tongue are no longer rare. "Cold sores" and "canker sores" which resist the usual remedies should be regarded with suspicion. In the oropharynx is presented a field of great importance in the general physical examination of all patients. Careful inspection here will often show the presence of certain small stellate cicatrices in the mucous membrane which prove veritable X-rays in revealing an all important truth through the dense opacity of conflicting history and symptoms. Primary lesions in this region are not rare, and the danger of infection here is shown by a case reported by Julian, in which a girl of seventeen years had both tonsils infected from the nipples of a recently delivered woman who had received the disease from her husband. Arlau of Padua has reported a very interesting case of persistent angina of the left tonsil in a woman, thirty years of age, the mother of two healthy children, and of exceptionally good history. He finally excised the tonsil, which had broken down, and the operation disclosed the presence of a chancre in the depths of the tonsil. In such cases the tonsil becomes much indurated, and the neighboring glands, especially those on the affected side, become unusually large, dense, and tender.

The occurrence of secondary pharyngitis, usually means that the general disease has continued from six weeks to three or four months. I have often been surprised, however, to observe, a pharyngitis, presenting the usual secondary characteristics, yield to specific treatment when the history extended over a period of years. Here, also, no hard and fast lines can be drawn clinically between the different stages, and this should always be borne in mind in the determination of a proper method of treatment. As a rule, when there is found in the pharynx an excessive hyperemia, with an evenly distributed edematous swelling over the palate and fauces, and presenting a sharp line of demarcation, the presence of syphilis should be suspected. These appearances may, however, occur in other diseases, and the order of the secondary manifestations may also change. In a case in which syphilitic infection was doubtful, and in which I very carefully ob-

served the symptoms, rapid disappearance of both tonsils by ulceration and without pain was the earliest secondary sign observed.

Tertiary manifestations occur in this location as gummata of the hard and soft parts, most frequently observed in a process of ulceration. They usually respond promptly to local and general treatment.

In the larynx the various manifestations of syphilis, simple catarrh, diffuse infiltrations, gumma, ulceration, cicatrices, with fibrous adhesions, perichrondritis, and paralysis all present certain characteristics which, together with the history, general examination, and results of treatment, make the diagnosis reasonably certain; under certain conditions, however, differentiation may be a problem presenting serious difficulty. In this connection a case reported by Dr. C. H. Knight[1] shows an interesting complication:

> The patient, a young student, presented typical signs of tuberculous laryngitis, and the diagnosis was confirmed by the presence of tubercle bacilli in the sputum. The patient went to California where he at first improved but soon become worse. A suspicious ulceration developed in the pharynx, and under mixed treatment there was prompt and permanent improvement in the local as well as in the general condition.

With regard to treatment it would seem that all authorities are agreed upon mercury and iodin as the two great remedies, though they are doubtful as to the advisibility of using these drugs as reactionary agents, fearing the existence or non-existence of syphilis. The relation between early treatment and tertiary manifestations is another subject receiving serious attention and study by the great syphilographers of the day. In this connection, the difficulty of obtaining reliable data is obvious, and it will only be by means of the collective experience of many observers, covering a long period of time that such data will be obtainable.

Finally, in the physical examination of a patient about to receive mercurial treatment, an exact knowledge of the condition of the kidneys may be of vital importance; for next to the intestines these organs are chiefly concerned in the elimination of mercury. Brouardel of Paris reports an interesting case in this connection, in which a woman, after taking the first mercurial pill was seized with stomatitis and alarming uremic symptoms. On examination the kidneys were found to be diseased, in consequence of which the drug was not properly eliminated.

It seems possible that an examination of the urine at the beginning of treatment, and at frequent intervals during the course of the disease, might reduce the number of cases reported as "syphilitic nephritis."

CLINICAL MEMORANDA.

REPORT OF THREE CASES OF ADIPOSIS DOLOROSA

BY WILLIAM G. SPILLER, M.D.,
OF PHILADELPHIA;
PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM IN THE PHILADELPHIA POLYCLINIC.

BUT a few cases of this disease, described and named by Dercum, have been reported, and it may be well to record three which the author has had the privilege of studying, even though nothing definite can be said concerning the pathology of the affection. Two of these cases have been studied with Dr. Dercum, and their histories have been obtained from him; the third was a patient of Dr. Mills. The writer is indebted to these gentlemen for the reports of the cases. Repeated opportunity for observation of Dercum's first case of adiposis dolorosa has also been given. All three patients, whose clinical histories are herewith published, are women, and at present, at least, the disease seems to be more common in the female sex.

FIG. 1.

Cross section of muscle from a case of adiposis dolorosa showing no appreciable change from the normal, except, perhaps, a slight enlargement of the nuclei.

CASE I.—Miss A. B., aged twenty-nine years, was referred by Dr. Rudolph Matas of New Orleans to Dr. Dercum. The family history was negative. Her father and three brothers were living and well. Her mother died in confinement. She had the various diseases of childhood, but never any nervous affection, and was well in early youth. The history of the present trouble was obtained from the patient herself, and is as follows:

About seven years ago, while walking along the street, she felt a sharp, sudden pain in the arch of the right foot. It was of a neuralgic nature and prevented her, for a few moments, from walking to a car. It continued for an hour or so and then disappeared for some days; but from that time on she was subject to more or less severe attacks of pain in the right foot. After a year or two, she consulted a physician who pronounced the disease rheu-

matism, and prescribed salicylic acid. Four years ago she noticed that her right lower limb was swollen at the ankle and also just above the knee. Finally, as she was not getting better, and observing that the entire extremity was growing noticeably larger, she went to another physician who also pronounced it "rheumatism of a neuralgic order" and prescribed salicylic acid. He directed her to bind her entire limb in a surgical bandage from the hip to the toes, to reduce the swelling. This she wore for about four weeks, but without satisfactory result.

At this time the pains in the leg were quite as severe as that in the foot, and they began to materially interfere with walking. Standing or walking markedly increased the pain. While in Canada last September she took a severe cold, and for two weeks could neither walk nor raise her right arm, as the pain also affected the right shoulder. Electricity, baths, massage, and a visit to Hot Springs all failed to make an impression upon the disease. Tingling sensations, at one time present in the toes of the right foot, disappeared, but in other respects the affection became more pronounced, the swellings increasing in size and number until the right limb was much larger than the left. In a letter from Dr. Matas the statement is made that at his first examination the pain was distinctly marked along the paths of the external cutaneous, anterior crural, and musculocutaneous nerves.

The clothing having been removed and the patient placed upon her back the right thigh was at once observed to be decidedly larger than the left. The left thigh and leg were full and well formed. The trunk, shoulders, and arms were also well rounded, but did not give the impression of obesity. In other words, the left leg, trunk, both shoulders, and arms were well formed and well proportioned. On palpating the right foot a small spot, exquisitely sensitive to pressure, was discovered immediately over the distal third of the instep, extending slightly over the first metatarsal bone and first interosseous space. It was not accompanied by any swelling. Behind the external malleolus another small area of tenderness was discovered, and here, in addition, a soft fatty swelling was observed. The circumference of the ankles, the tape lying over both malleoli, was a quarter of an inch greater in the right than in the left foot. By measurement the right leg was also found to be somewhat enlarged. Thus, at the junction of the upper and middle thirds, the right leg measured 13⅜ and the left 12¾ inches. The enlargement appeared to be diffuse and uniform; no nodules, defined masses, or painful areas were detected. The enlargement of the thigh was very striking and readily confirmed by measurement. At the junction of the lower and middle third the right thigh measured 19⅜ and the left 17⅞ inches. At the junction of the middle and upper thirds, the right thigh measured 22¾ and the left 22¼ inches. The middle third of the right thigh measured 21½ and the left 19¾ inches. The enlargement of the thigh was found on palpation to be unevenly distributed. Immediately over and above the internal condyle, for example, an area was found at which the enlargement was more pronounced, and which felt nodular or lumpy. At this situation great pain was elicited by pressure. Upon the outer aspect of the lower third, several small, nodular, painful masses were also detected. In addition several painful areas were found in the course of the external, middle, and internal cutaneous nerves.

Some enlargement was present above the thigh, that is, over the lumbar and also to some extent over the right gluteal region. The enlargement had taken place, as far as could be judged, only in the fatty tissue. Over the right iliac crest, and to some extent posteriorly, a striking enlargement about the size and shape of a large orange was noted. This mass presented the same nodular (worm-like) feel noted in other situations. It was exquisitely painful, and not sharply circumscribed, but shaded off into the adjacent fatty tissue. The soreness was so great as to prevent the patient from lying upon her back or upon the right side. The entire lateral aspect of the right buttock was very sensitive to pressure, the pain interfering with the patient's sitting in a chair. A soft, more or less circumscribed mass was found in the right popliteal space. No nodules were discovered in any other portion of the body save on the inner aspect of the left arm, where a small mass, the size of a large nut, was detected.

The patient was a well-nourished young woman with a rather good color. There was no history of hemorrhage from mucous surfaces, or of cough or dyspnea. There was no headache. Backache, however, has been present at various times. Menstruation was normal.

The patient stated that the pain was never absent in the fatty masses, and that they were always more or less tender. At times, however, great exacerbation of the pain occur. In other words, the pain was subject to paroxysmal exacerbation, and she had repeatedly observed during these periods that the various nodular swellings above described had a firmer and somewhat indurated feel and were distinctly increased in size. After the paroxysm of pain subsided the intensity of the swelling somewhat diminished, but it never entirely disappeared. She further stated that each attack of pain seemed to add permanently, though slightly, to the size of the swellings. It was evident, from the examination, that the swellings were in the fatty tissue. There was no involvement of the muscles or bones.

CASE II.—M. A., an unmarried woman, aged sixty-five years, born in Ireland, was admitted to the service of Dr. Dercum at the Philadelphia Hospital, November 25, 1896. She was a very stout woman, and complained of pain in her feet. Her mother died of dropsy at the age of fifty years; her father was drowned. Three brothers and three sisters died in infancy. One sister grew very stout after the menopause, and finally died of asthma.

The patient had always been very healthy. She denied alcoholism. Menstruation ceased at forty. She had formerly been thin, but began to grow gradually stout at about the age of forty. She worked in a laundry during twelve years, and at the end of this period began to have pain. The pain was first felt beneath the heels, especially on walking. This pain extended to the legs, and seemed to be in both flesh and joints, later in-

volving the hips and right shoulder. Two years ago (1894) she noticed pain in the fatty tissue of the limbs and trunk. She had never vomited blood nor had hemorrhages; she had not had headache or vertigo. The pain in the fatty tissue was subject to paroxysmal exacerbations. She stated that she had grown much stouter since the pains began.

Tenderness and pain were elicited by pressure, and upon handling the fatty tissue of the arms, thighs, legs, buttocks, lumbar region, and back. Slight soreness was also detected over the abdomen, the right shoulder, and the right arm, both inner and outer aspects, and local weakness was also observed. The pain did not follow any nerve distribution, and there was no anesthesia. The response to tests for heat and cold was prompt and correct. The patellar reflexes were normal. The tongue was protruded in a straight line. The pupils were equal and normal. The patient complained of headache and pain during motion of the left hip-joint, the latter having continued three years. She had also a marked flush over the forehead. The obesity was very marked over the thighs, calves, abdomen, nates, and back. It was also very great in the arms, less marked in the forearms, and absent in the feet and hands. In the face there was no special deposit of fat and no pain. The same condition was present in the neck. The isthmus of the thyroid was exceedingly small. The presence of lumps was not noted in this case, as in Case I.

CASE III.—Mrs. A., aged forty-five, referred to Dr. Mills by Dr. Thomas Hay of Milwaukee. The patient stated that there was no history of a trouble similar to hers in her parents or in their families. Her mother had had rheumatism which caused a very different kind of pain. A daughter of the patient's was in delicate health, but did not have a similar disease, and her three children were healthy.

The patient had been corpulent twelve or fourteen years, and first began to gain fat when she was about thirty-five years old, after the birth of her last child. She weighed 116 pounds at the time of her marriage, and during the four years previous to coming under observation weighed about 192 pounds. After an attack of pain she was always more fleshy and could not wear her clothes. The pains began about four years ago, at a time when she was rapidly gaining fat. The history of the commencement of these pains is as follows:

The legs from the knees to the feet began to ache, especially at night, and she could not sleep. After three or four weeks she had a sensation as of worms creeping in the flesh below the knee, and this made her exceedingly nervous. She also had a sensation of a tight band wound about the right lower limb from the lower part of the thigh to the foot. The calves of the legs felt as if they would burst open.

These symptoms continued for several months until she had an attack of very severe pain with a sensation of burning in both lower limbs, attended by a difference in the degree of temperature on the outside and inside of the thighs, as tested by her own hand. About three months later the pains were felt in the right arm, and some months later in the left.

During the first attack she noticed small pea-like swellings beneath the skin of the thighs, legs, and feet, but not in the arms. She had had severe attacks of pain, attended by painful swellings, at irregular intervals, but had been free from them as long as two years at a time. About four years ago nodular swellings were noticed on both sides of each knee, but were more marked on the right limb. These gradually grew smaller. At one time she had a large lump in the left inguinal region, which increased in size and was more painful at her monthly periods. This subsequently disappeared. She had also, at one time, a painful swelling over the back of the left hand.

Massage benefited her greatly, and under treatment with thyroid extract she improved so much that she became much thinner, and last summer could walk a block and a half. Her headache, from which she suffered greatly four years ago, is at present much less severe.

This patient had never had pain in the face. Often during her attacks of pain the palms of the hands and the soles and sides of the feet were covered with blisters, and after the attacks were over the skin peeled "as in scarlet fever."

On examination the patient was found to be corpulent, but not nearly as heavy as the patient first described by Dercum. A small lump was found on the outer side of the right knee. She complained of much pain in the lower limbs and to a less extent in the upper. This pain was spontaneous and was increased by pressure, and did not follow the course of any nerve. The hands and feet were somewhat puffy, but did not pit on pressure. The face was not affected and was not tender to pressure, except above the eyes. The patellar reflex was obtained in the left leg, but not in the right, even by reinforcement. There was no ankle clonus. Sensation for pain and touch was everywhere normal. There was no limitation of the visual fields, as tested with the hands. Except over the coccyx there were no painful points along the spine. There was no inguinal tenderness (ovarian), but there was slight inflammatory tenderness on the right side, and still more tenderness on the left. The limbs were everywhere tender to touch, and the back and front of the trunk were also tender, but not to such a degree as the limbs.

A CASE OF INGUINAL HERNIA OF LARGE SIZE; CURE FOLLOWING AN UNUSUAL METHOD OF OPERATION.

BY A. ERNEST GALLANT, M.D.,
OF NEW YORK;
ASSISTANT, DEPARTMENT OF SURGERY, IN THE NEW YORK POLYCLINIC.

DURING April, 1895, Mrs. M. N., aged sixty-two years, was referred by Professor Van Arsdale from the Good Samaritan Dispensary to the Lebanon Hospital. Her history was as follows:

Twenty-six years ago, while at work, she felt a snap, and something seemed to give way in the left groin, following which a small mass made its appearance in the region referred to. With the birth of each of her four

children the mass increased in size. During recent years she has had three attacks of so-called "strangulation," the last two occurring two months before admission to the hospital. Bandages and supports of various kinds had been tried, and failed to afford any relief. She finally became practically bedridden, and, fearing another period of complete obstipation, was willing to submit to any precedure offering a chance of relief.

The operation was performed May 22, 1895, an incision six inches long being made over the anterior part of the tumor. Later, the opening was enlarged upward and outward toward the anterior spine of the ileum in order to facilitate reduction and suturing. The thin-walled sac contained the greater portion of the transverse and descending colon and nearly all of the small intestine. A portion of the small intestine fifteen inches long was adherent to the most pendulous portion of the sac, and was released with difficulty. The abdominal cavity, being relieved for so long a period of such a large portion of its contents, had contracted to such an extent that reduction was very difficult, and, when finally accomplished, made the abdominal walls as tense as a drum. While the intestines were being replaced, Dr. Parker Syms cut off the sac close to the groin, leaving only sufficient tissue to cover the wound.

Fig. 1.

Inguinal hernia in a woman.

The condition previous to operation is well shown by the accompanying illustration (Fig. 1). Through the thickened inguinal ring the patient could reduce the mass to about one-half its usual size. She was examined by the members of the visiting staff of Lebanon Hospital, and all agreed that, in view of the liability to obstruction or strangulation, operative interference was justified, as likely to afford relief for a time at least, though cure could hardly be expected.

Owing to the weakness of the patient's pulse, no attempt was made to cover the raw surface which remained after the separation of the adhesions. Anticipating very great abdominal tension it occurred to me that the following method of introducing the sutures could be more quickly applied, and perhaps more likely to hold than the usual method of uniting corresponding structures. Kangaroo tendon was employed for the buried sutures. The sutures were passed through the upper border of the wound, including the peritoneum, transversalis and external oblique muscles, and then, *inside the abdominal cavity*, through the peritoneum just above Poupart's ligament. The external oblique muscle and fascia were stitched edge to edge, *én masse*, to all the structures which compose Poupart's ligament. By this means the second tier of sutures overlapped the first by about one inch. The skin wound, twelve inches long, was sutured with silkworm gut.

On the afternoon of the second day after the operation the patient presented a marked degree of tympanites. Twelve doses of epsom salt, 1 dram each, were given. This was followed during the night by enemata of soapsuds, and later by a high injection of turpentine and sweet oil, but without affording any relief. At this time Dr. Syms telephoned that the patient was suffering from intestinal obstruction, and instructed me to operate for the relief of that condition. The abdomen was extremely distended, and the patient in great pain and fearing death.

After the removal of the dressing light friction was applied to the abdomen with the palm of the hand, beginning at the right iliac fossa, passing along the course of the colon to the opposite side, down to the region of the segmoid over the pubes. This maneuver was slowly and constantly repeated, and, after a few moments, the abdomen became less tense and the pain subsided. With the closed fist greater pressure was now exerted, and within fifteen minutes considerable gas was passed from the rectum. The patient expressed her appreciation of the relief afforded by kissing the hand of the masseur, shortly after which she went to sleep. During the day the bowels moved four times. No further difficulty was experienced. Healing of the wound took place by primary intention. The highest temperature reached at any time was 99.6° F.; pulse, 88. During the period of abdominal distention the respirations reached 52 per minute. Since leaving the hospital the patient has been able to attend to all her domestic duties, washing, ironing, scrubbing, etc.

During March, 1897, the patient changed her residence, and since then I have been unable to locate her, but at that time, twenty-one months after operation, she was in excellent condition.

This patient may be regarded as cured, and the writer feels that the good result was due to (1) the method of introducing the sutures, and (2) to the prompt relief of the intestinal distention by means of friction, a procedure which has proven useful in many cases.

A Victim to the Plague.—Madame Florence Morgan, the superintendent of the Plague Hospital at Bombay, recently died at that place of bubonic plague.

MEDICAL PROGRESS.

Tuberculous Ulcer of the Inner Surface of the Cheek.—CARRIERE (*Monats. f. Pract. Dermat.*, vol. XXVI., No. 1) describes the beginning of tuberculosis in a patient, aged thirty-seven years, who came to him for treatment of a slight abrasion on the inner surface of the left angle of the mouth. In the course of a few days this healed, leaving a somewhat elevated scar. Soon after, in this scar, an ulceration appeared and extended gradually backward 2.5 inches parallel to the margin of the teeth, where it presented the appearance of a raised lesion with sharp whitish edges. It was not painful, but was exquisitely tender if disturbed. The surrounding mucous membrane was normal in appearance. Tubercle bacilli were found to exist in the margin of the ulcer.

Amputation of the Leg below the Line of Demarcation.—ALLEN (*Med. Record*, December 25, 1897) describes a case of typhoid fever followed by gangrene of the left leg, apparently due to thrombosis. Owing to the very weak condition of the patient, amputation under an anesthetic was rejected as likely to prove fatal, and poultices were applied. As soon as demarcation was established, the patient was given a small dose of chloral, and without her knowledge the leg was amputated through the gangrenous tissue. Six months later, the flaps were split up, the bones divided at a higher plane and their ends covered. Union was this time primary, and the patient entirely recovered. This rather tedious method of procedure, in Allen's opinion, saved a patient who under any other plan of treatment would have succumbed.

THERAPEUTIC NOTES.

Antiseptic Treatment of Acute Otitis Media. — CHEATLE (*Pediatrics*, January, 1898) urges the importance of antiseptic treatment of the external meatus in cases of middle-ear trouble. The cartilaginous portion of the meatus teems with micro-organisms. The writer has observed that in acute otitis media puncture of the drum membrane is frequently followed by the escape of serosanguinous fluid without pus. Even if pus is present, if possible, further infection should be prevented. The first thing to be done when consulted by such a patient is to purify the auricle and meatus. This is best performed by means of a 1–20 carbolic-acid solution. Small swabs of cotton are dipped in this, and with them the meatus is thoroughly scrubbed. The ear is also douched with a 1–40 carbolic-acid solution. When the meatus has been thus purified, a light plug is introduced into it, and a dressing and bandage applied. If it subsequently becomes necessary to puncture the membrane this may readily be accomplished without infection, and even if this does not become necessary, the dressing gives the ear functional rest, a point the value of which is not sufficiently appreciated. Carbolic acid is a particularly good disinfectant in these cases on account of its anesthetic property, and its power of penetration into fats. Patients with middle-ear disease, if treated in accordance with these principles, do very well indeed.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, FEBRUARY 26, 1898.

DOES PUBLICITY INCREASE CRIME?

WHEN the medical student reaches cardiac diseases in the course of his studies he frequently discovers that he has a systolic murmur or some other alarming symptom of heart disease. This fact is so well known that it has passed into that most ancient of all storehouses from which the college professor draws his jokes. Is this harmless form of "suggestion" a true index of the effect on the public of a constant presentation to their minds of the details of crime? Do the sensational reports of murders, of rape, of arson, incite other men and women to like deeds? Is crime infectious and contagious?

Warren, in discussing this subject in the January number of the *University Medical Magazine*, asserts that newspapers propagate crime in three ways: (1) by suggestion, (2) by creating an insane desire for newspaper notoriety, and (3) by placing a premium on crime. The newspaper stands in about the same relation to the public, according to this writer, as a hypnotist does to his subject; and while there is some doubt whether a hypnotist can by suggestion induce a person to commit crime unless he already has a leaning in that direction, still there are too many individuals who are willing to be persuaded into wrongdoing, especially if they hope to profit by it, to make that excuse of much avail.

As for the effect on the would-be criminal of seeing his name and photograph in the "Extra" of a penny print, there is much direct testimony that boys and others, who have committed some horrible crime such as train-wrecking, were impelled to it by the love of notoriety. Imagine yourself a criminal, considering the chances of being caught if you carry out a certain daring burglary. What would be the relative deterrent effect upon you of the methods of trial and publicity in this country, and, for instance, in Germany? The conditions here do not require description. On the other hand, in Germany, the prisoner drops out of existence, one may almost say, until the result of a secret trial has either released him or separated him still further from all contact with his fellows. It cannot be denied too, that in Germany the scarcity of mercy would have a still further deterrent effect upon intending criminals; but the difference in this respect in our own country is, in no small degree, the result of the habit we have grown into of looking upon a criminal trial as a contest, and if the criminal makes a plucky fight, or if the odds are heavily against him, the love of bravery and fair play, makes both jury and public unwilling to decide against him, irrespective of the crime which has brought him into the lists. The remedy for this state of affairs proposed by Warren, is to ask the representatives in Congress and in the Legislatures to pass laws prohibiting the publication of this class of news.

In the *Public Health Journal* for December, Humphrey of Oregon, takes up the increase of crime from a little different point of view. He too, admits the increase of crime (there were 48,834 murders and homicides in the United States in the ten years ending 1895), and laments the ineffectual means of prevention which are now employed. Impressed as he is with the fact that criminals to a great extent breed criminals, he advocates the asexualization of old offenders, as the most logical measure to protect the State from an ever-increasing number of individuals having a well-marked criminal tendency.

As to the practical outcome of such a law, he says:

"Criminals would regard such a law with terror, and would rather take their chances against anything than having their procreative organs removed. I

am aware that a great many will not agree with me, but I have the courage of my convictions and can afford to be criticized. Of all the criminals that should be so dealt with for the first offense are those who rape innocent women and girls. All other classes might be subjected to the operation of such a law on a second conviction."

The study of anthropology has proved the existence of a criminal type, with marked characteristics in anatomy and physiology. How fruitless to allow these parasites upon society to multiply, and then to spend millions in the attempt to alter these characteristics in the individuals of ever-recurring generations! And every year while the Government is performing this task of Sisyphus, thousands of good members of society are robbed and butchered by the degenerated who ought never to have been generated.

EXPERT MEDICAL WITNESSES.

A BILL has been introduced in the New York Legislature which aims to provide for the examination and appointment of medical expert witnesses in certain cases, and for the regulation of their compensation. The act is fostered, it is understood, by the Homeopathic State Medical Society.

The essential features of the bill are: That upon the trial of all indictments for felonies in a court of criminal jurisdiction, whenever it is made to appear to the Court that the trial will probably require the introduction of medical testimony, the Court may, upon application of either party, appoint such a number of experts—not less than three or more than five—as the Court shall deem proper. The presiding judge shall provisionally prepare a list of names of such persons as it may have reason to believe properly qualified, and shall cause any of these persons to be subpœnaed to appear at such time and place as the judge may order. They shall then be examined by the latter, touching their qualifications to serve as experts, and if they pass a satisfactory examination they may be employed; if they do not, they are at liberty to return to the duties of their profession, with which they believe themselves competent to cope and which the licensing faculty has deemed them fitted to perform.

If the individual who has been preemptorily summoned from his chosen labor satisfies the presiding judge that he has sufficient "expertness," he is to be paid from $10 to $100 a day for his services, depending upon the value which the all-wise Solon who then happens to wear the ermine puts upon his services. He is also allowed mileage, the same as other witnesses. As the bill provides that experts may be summoned from without the State, it may be well for experts living or sojourning in the Occident to enlarge their strong boxes and make plans now for the repletion of their exchequers. The only other feature of the bill which calls for remark is, that nothing in the act shall be construed to limit or effect the right of either party to summon other expert witnesses—as many as they may be able to induce to give testimony on a contingency, or a cash basis.

No one will deny the opportunities of the time, nor the necessity of reform in the present method, or want of method, of employing medical expert testimony. There has already been much useful discussion on this topic, and it is not improbable that in time a plan will be evolved which will be a great advance on that in vogue at the present day. We regret, however, to say that the bill in question does not contain a germ of laudable or legitimate reformation, and we hope sincerely that every physician who is interested in this matter and every society to whose Committee on Codes it will be referred, will do all in their power to prevent its enactment.

The first, if not the most serious, objection raised to the act is, that it leaves the power of appointment of experts in the hands of the presiding judge. This individual may be deeply learned in the law; he may be profoundly versed in the humanities; he may be an honest, upright, judicial personage; but wherefore should he know of the weary delving into the realms of science, and of the years of studious labor on the part of physicians, whom he does not know either by word or reputation, which give them the right to be called "expert" by their professional brethren? As a matter of truth, he does not know, nor in all human probability has he any ambition to extend his knowledge in this direction. One of the speakers discussing this subject at the meeting of the State Society a few weeks ago in Albany, said that it was notorious that judges selected their physicians from the ranks of the homeopaths or the quacks, and it was the exception for a

judge to have in his service a reputable, distinguished physician. If they cannot be relied upon to show greater wisdom in the selection of their family physicians why should they be expected to be more perspicacious and discriminative in behalf of the public?

A second objection to the bill, and one that more closely concerns the physician, is that no law that compels him to relinquish whatsoever he may be engrossed in, even though it be of the gravest import, and dance attendance upon a court which shall examine him as to his fitness to testify on a matter which may not be of the slightest interest to him, can be enforced. The "expert" may be called upon to give testimony that spares a human life, or to testify to facts that will keep in the hands of legitimate legatees millions of dollars, and for this service he is given $15, or $40, or even, if Magnanimity is sitting on the bench, $100. For this paltry sum he has burned the fires of his soul and pigmented his cortical cells, that a judge may rise up and call him expert. No wonder that the legal faculty look upon the doctor as an easy prey, when there are those amongst us who assume the rôle of reformers and put the value of a journeyman plumber's wages upon their services. Imagine employing Daniel Webster, Henry Clay, and Rufus Choate, in their day, or in ours, for from $10 to $100 a day. Shades and spirits of these immortals gather around and protect us! Yet this bill proposes to call, at any time or place, the leaders of the medical profession, the authorities of the day, and, after using them to their advantage, requite their services with a contemptible sum which not even the most inconsequential lawyer would deign to accept as a retainer.

And lastly, when the whole matter is simmered down, of what earthly benefit would the enactment of such a law be? It states specifically that either party may call as many experts as he sees fit. Modern Crœsus, accused of crime, may summon the flower and fruit of the medical faculty, and so bewilder his twelve peers sitting in judgment upon him that the trial would be an exact counterpart of those of to-day. On the other hand, an impecunious, miserable wretch, on trial for murder, might with her nescient wail, touch the sympathetic cord of a hysteric sisterhood, who, under the guidance of crafty counsel, would erect a psychic superstructure of fantastic epilepsy that, through the mediumship of outside experts, would sweep her from the electric chair.

If we are to have reform in the matter of expert medical testimony, let us have reform based upon sound reasoning and legitimate principles of equity and honesty.

MEDICAL POLITICS AT MOBILE.

We had not given any credence to charges made in certain papers that the quarantine convention intended to be composed of delegates from the South Atlantic and Gulf States, which met in Mobile on February 9th, 10th, and 11th, was, as specifically charged by them, a "packed" convention conceived by persons inimical to a national quarantine, and incidentally opposed to the development of the Marine Hospital Service. The fair appearance of the call, the equable division of representation among the Southern States, and the high character of some of the gentlemen named as its leading spirits, seemed to forbid such a conclusion; but the reports which we have at hand from this meeting indicate that the elaborate program laid out by its astute managers to discuss the varied features of maritime and interstate quarantine and sanitation in general was nothing more or less than a Barmecide feast.

The ingenuous gentleman who went to the convention under the impression that he would hear scientific papers and discussions on the diagnosis of yellow fever, the sanitation of cars, baggage, and freight in times of epidemic, the disinfection of houses and other similar topics of vital interest, soon found that while the politics of the managers of the convention necessitated this masquerade to attract attendance, the real interest of its promoters was to secure an endorsement of the so-called American Medical Association bill to establish a Department of Public Health, and to denounce the Caffery bill which has been drawn in the interest of Federal quarantine. We learn that the Executive Committee, a self-appointed body, selected a permanent Chairman for the convention without giving the members the privilege of voting on the presiding officer, and that this same Chairman thereupon named a Committee on Resolutions, who were to formulate the sentiments of the convention upon the all-important point of national or State supremacy in quarantine matters.

Although this convention was to be composed of delegates from the South Atlantic and Gulf States, it was soon discovered that Illinois was represented by the editor of the *Journal of the American Medical Association*, and Wisconsin by the Chairman of the Committee of the American Medical Association, by which was formulated the bill designed to obliterate the Marine Hospital Service in national health matters. Delegates were also present from New York, Maryland, and Kentucky, and these gentlemen and the delegates from these three States were accorded equal privileges on the floor, and were appointed members of the Committee on Resolutions, a body of thirteen members, of which these constituted almost one-half. The rest was easy, and although the managers did not secure an endorsement of their bill, neither did it secure a denunciation of the Caffery bill, as there was a large minority, who, in their disappointment at the outcome of the convention, did not propose to be led further into a game which had become manifest at the close of the third day. One day of scientific discussion and two days of wire-pulling had opened their eyes to the meaning of the convention. What the convention resolved,—a sort of endorsement of national quarantine, with a reference to the reserved rights of States,—is highly unimportant even if it was unanimously passed. In fact, the New Orleans *Times-Democrat*, in its issue of February 12th, says editorially "unless Congress can do better for the South Atlantic and Gulf States than the convention proposes that it shall do," referring to these resolutions, "their liability to invasions of foreign disease will not be materially lessened."

ECHOES AND NEWS.

Monument to Tarnier.—The former pupils of the late Professor Tarnier have formed a committee to secure funds for the erection of a monument to his memory.

An Enormous Heart.—At an autopsy recently held in London (Eng.) to determine the cause of death in the case of a man, forty-six years of age, who had suddenly expired in an omnibus, it was discovered that his heart weighed forty-three ounces.

Another Achievement in Abdominal Surgery.—Mr. Frederick Treves, the English surgeon, recently removed the whole of that part of the bowel below the transverse colon, together with the anus, in a case of idiopathic dilatation of the colon in a child. The patient made a good recovery.

Hospital Service for Alaska.—A company known as the Alaska Sanitary Company has been organized under the laws of Illinois for the purpose of establishing a series of hospitals at all the important points in Alaska. The chief promoter of the enterprise is Dr. F. H. Booth. A two-story log structure has been erected at Dawson City as a hospital. The institution is under the charge of Father William Judge of Baltimore. It has twenty-six patients. At present the nursing is done by the miners, but six sisters of St. Anne are on their way from Montreal to act as nurses and teachers.

A New Location for Mt. Sinai Hospital.—A site consisting of twenty-five lots on Fifth avenue between One Hundred and One Hundred and First streets has recently been purchased by Mt. Sinai Hospital of New York, upon which a new building is to be erected in the near future.

Sterilization by Frying.—Olive oil at a temperature of 256° F., is recommended for sterilizing syringes and instruments. Immersion for an instant in the hot oil will completely sterilize an instrument, while to render a syringe germ free, it is only necessary to twice fill the barrel with oil at the temperature mentioned.

Funds for the Craig Epileptic Colony.—Among the bills recently passed by the New York Assembly is one appropriating $161,000 for the Craig Colony of Epileptics. This experiment in the management of epileptics may now be considered an established system, and the recognition of this fact by the State legislators is thus assuring it substantial aid.

The Middleton Goldsmith Lecture.—The Middleton Goldsmith lecture of the New York Pathological Society was delivered at the New York Academy of Medicine on Friday evening, February 25, 1898, by Professor William T. Sedgwick of Boston. The subject was: "The Establishment and Conservation of Purity in Public Water-supplies, Especially Those of Great Cities."

Expectoration Tracts.—The Women's Health Protective Associations in different parts of the country have extended their warfare against expectoration in public buildings and street-cars by the distribution of neat little cards which invite the attention of the offender against public health and cleanliness to the fact that expectoration is forbidden. These cards are already in use in Boston.

To Abolish Coroners.—The first county to seek to take advantage of the omission of any mention of the office of coroner in the new constitution is Ulster, and Assemblyman Tremper has introduced a bill abolishing the office in that county. The measure is now awaiting its final reading in the Assembly. If the bill passes, it is expected that a number of other counties will follow suit.

An Instrument with a History.—The museum of the Royal College of Surgeons of England has been enriched by a case of instruments which has a distinct historic value. The case contains a saw which bears this inscrip-

tion: "The first subcutaneous osteotomy saw made by Mr. Blaise, and used by Mr. William Adams on December 1, 1869, in his first case of division of the neck of the femur."

"Undesirable Invalid's Bill."—According to the *Lancet*, this is the title of a bill which it is proposed to bring up for the second time before the House of Representatives of New Zealand, The bill is directed against the landing on the islands of patients afflicted with communicable diseases, and stringent measures are to be adopted with regard to those people already in the colony who are similarly afflicted. Foremost among such diseases is tuberculosis, and more particularly pulmonary tuberculosis.

Scarlet Fever from Milk.—Some cases of scarlatina at the Oranges, New Jersey, are reported to have been traced to a dairy conducted by a family, all the members of which have been, or are now, suffering from that disease. The dairy is at Northfield and has been taken in hand by the State Board of Health. The cows have been given a clean bill of health and are now at another farm. The nature of the attack was not understood by the family until the first patient, a person over sixty years of age, had passed into the desquamative stage.

Female Candidates for Fellowship.—Among the list of candidates for fellowship of the Royal College of Surgeons, Ireland, appear the names of three women who present all the qualifications prescribed by the College and recognized by the General Medical Council. In conformity with collegiate rules the applications will receive attention with a view to inquiry as to the eligibility of the applicants in other respects, and it is assumed that if no objection is then offered, they will be admitted to the examination. Whether they will achieve the fellowship is another question.

Improved Methods of House Disinfection.—The question of what to do with people who live in two or three rooms when a case of infectious disease necessitates closing these up for disinfecting purposes, has been solved in England. Upon the suggestion of the medical officer of health, Dr. Waldo, the vestry of St. George's, Southwark, have opened a receiving house for the reception of the temporarily homeless families. They are taken care of at the receiving house for eight hours, during which time they are given baths and their clothing is taken from them and disinfected.

Examinations in Hygiene.—Rutgers College is the first educational institution in this country to definitely recognize the specific qualifications of sanitarians. The college will conduct examinations and grant certificates in municipal hygiene to officers of local boards of health, sanitary inspectors, factory inspectors, plumbing inspectors, and to those who may seek appointments to these positions. The examinations, which will be held on the first Wednesday of the months of March, June, and October at the college buildings in New Brunswick, New Jersey, will be designed to test the fitness of persons who may by called upon to engage in the execution of the health laws.

Obituary.—Dr. John G. Truax died at his home in New York on February 16th of Bright's disease and heart failure. Dr. Truax was born in Oneida County, New York, in 1848. From the University of Michigan he went to Rush Medical College, Chicago, and was graduated from that institution in 1871. He came to New York in 1876. He was a brother of Judge Truax of the Supreme Court.—Dr. Robert A. Wheaton recently died of apoplexy at his home in St. Paul, Minn., at the age of thirty-five. He was a graduate of Harvard, and was professor of minor surgery in the University of Minnesota, and captain and assistant surgeon in the Minnesota National Guard.—Charles Todd Quintard, D.D., LL.D., Bishop of the Protestant Episcopal Diocese of Tennessee, died last week at Meridian, Ga., of heart failure. He was born in Stamford in 1824. After leaving Trinity School he studied medicine with Dr. James R. Wood and Dr. Valentine Mott, and was graduated from the University of the City of New York in 1847. He then removed to Athens, Ga., where he began the practice of medicine. In 1851 he was appointed professor of physiology and pathologic anatomy in the medical college at Memphis, Tenn., and was co-editor with Dr. Ayres P. Merrill of the *Memphis Medical Recorder*. In 1855 he was appointed a deacon in the Protestant Episcopal Church, and in January, 1857, became rector of the Calvary Church, Memphis. After the death of Bishop Otey in 1865, he was elected Bishop of Tennessee. He received the degree of doctor of divinity from Columbia in 1866, and that of doctor of laws from Cambridge (Eng.) in 1867.

Statement by Surgeon-General Wyman Regarding Ship Island Quarantine.—In a letter to the *Washington Post*, in reply to one asking for information in regard to the quarantine station on Ship Island, Miss., Surgeon-General Wyman says: "There is absolutely no place for the location of a quarantine off the coast of Mississippi to which greater objections cannot be made than are made to Ship Island. If a distance of twelve miles from the coast is an insuperable objection, then the quarantine stations at San Francisco and San Diego, Cal., Galveston and Sabine Pass, Tex., Mobile, Ala., Key West and Fernandia, Fla., Brunswick and South Atlantic Quarantine, Ga., Cape Fear Quarantine, N. C., and New York Quarantine all would have to be moved, for they are all nearer to the coast or to populated districts than is Ship Island. . . . Captain Laym of the Revenue Cutter Service and Surgeon Murray of the Marine Hospital Service were directed to visit the other islands in the Gulf, and reported under date, December, 19, 1883, that Ship Island was the best located and the only island which possessed the necessary advantages for a quarantine station. Nevertheless, in 1898 various influences brought about the act of Congress authorizing the removal of the station to some other island. This act of Congress gave authority, but was not mandatory in its language. A board was appointed March 10, 1888, to select a site for a new quarantine station, and though their orders required them to recommend some other site

than Ship Island, the board went out of its way, in the fourth paragraph of its report, inserted at the suggestion of Dr. Wilkinson of Louisiana, to state as follows: 'There is no evidence to warrant the belief that the presence of the National Quarantine Station on Ship Island is a real source of danger to the inhabitants of the Gulf Coast, but all testimony points absolutely to the fact that the absence of an efficient quarantine service at that place will afford a probable inlet to contagious diseases into that vicinity.' This report was signed by Surgeon W. H. H. Hutton of the Marine Hospital Service; Captain J. H. Parker of the United States Revenue Cutter Service; Dr. J. W. Mabin of Biloxi, who represented Mississippi, and Dr. C. P. Wilkinson of the Louisiana State Board of Health. The Board reported that Chandeleur Island afforded the 'next best' location, and accordingly the station was removed there in 1889, and, all told, about $85,000 was expended in its establishment. Immediately thereafter, the State of Mississippi established a quarantine at the abandoned site, performed active work there inspecting and disinfecting vessels, charging the customary fees therefor, and continued to do so with some intermission until 1894, when the United States establishment was replaced on Ship Island."

CORRESPONDENCE.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

PUBLIC OPINION AND THE TYPHOID EPIDEMIC—A LOW DEATH-RATE FOR 1897—METHYLENE BLUE IN THE TREATMENT OF GONORRHEA—PAPILLARY NEOPLASMS OF THE ILEUM—THE OXYTOXIC INFLUENCE OF QUININ—A LARGE BEQUEST TO THE PENNSYLVANIA HOSPITAL—THE ALIENISTS' REPORT ON A BOY MURDERER.

PHILADELPHIA, February 19, 1898.

PUBLIC interest in the typhoid situation has to some extent abated, in the face of other topics of the hour, and in realization of the fact that all agitation for the abatement of the pest by help of the city legislators is exertion uselessly expended. The people have expressed convincingly their opinions in the press, in mass meetings, and before Councils themselves, but to absolutely no avail in so far as securing an appropriation for an improved water-supply is concerned. So the question begins to become uninteresting to some, apathetic to others, and a wholly useless topic for discussion to all—the public, by a long apprenticeship, have grown accustomed to the prevalence of enteric fever, and they are inclined to look on it just as they look on the other preventable infectious diseases which we, in our much-heralded republican freedom, accept as necessary evils attending the present *fin-de-siècle* civilization. Public interest, it should be remarked, and not the interest of medical men, is on the wane. Physicians throughout the city continue to urge filtration, continue to demonstrate the wanton sacrifice in human lives which typhoid costs the city of Philadelphia, and continue to exert their every effort for the improvement of the situation, without, it must be confessed, very tangible hopes of success. It has narrowed down to this point: that Councils refuse absolutely to comply with the popular demand for filtration of the water-supply, and that the arguments of the people and of the medical profession may, like Tennyson's brook, run on forever, and never so much as wear the faintest indication of a groove of humanity or common sense in the cerebra of these "city fathers" of ours. The whole affair is disgusting to every fair-minded Philadelphian. The fever-pest still continues, with, however, a decrease during the last two weeks in the number of new cases, which improvement is offset by a much higher death-rate. During the week ending February 19th there were 156 new cases, with 17 deaths reported, as compared to 185 new cases, with 21 deaths, for the week of February 12th. Since the epidemic began 1839 new cases of typhoid, and 196 deaths from this cause have been reported to the Board of Health. Further comment is unnecessary to the intelligent; it is unconvincing to the opponents of the filtration bill.

In spite of the general increase in infectious diseases and of the increased death-rate from diphtheria and scarlet fever, the death-rate in Philadelphia for the year 1897 was but 18.72 per thousand inhabitants—the lowest rate for thirteen years. The total number of deaths from all causes and at all periods of life was 22,735, or a decrease of 1247 from the previous year. It is also gratifying to note that the death-rate last year in children under five years of age was the lowest ever attained here, the deaths at this period of life numbering 33.45 per cent. of the total number of deaths, in both adults and children, from all causes. This is attributed, in a large extent, to a better personal acquaintance on the part of parents with laws of sanitation and with hygienic measures, and to the extensive municipal improvements which have been made in the poorer districts of the city, where formerly improper drainage and careless house-inspection kept the infant mortality at a high figure. In this connection, also, the highest credit must be rendered to the various "fresh-air" organizations, such as the Red Bank Sanitarium and the Country Week Association, for their humane and indispensable labors in caring for thousands of the little ones of the alleys and slums during the heated months; the value of their work cannot be estimated too highly.

Horwitz, at the last meeting of the Philadelphia County Medical Society, related his experience with the treatment of gonorrhea with methylene blue combined with the oils of sandalwood and cinnamon and the oleo-resin of copaiba, together with urethral irrigations with permanganate of potassium solutions of a strength of from 1-2000 to 1-1000. Methylene blue was given usually in 2-grain doses three times daily, but as this quantity was found to produce strangury and slight diarrhea in about twenty-five per cent. of the patients to whom it was given, the dose, in such instances, was diminished one-half. The combination of powdered nutmeg seemed to prevent, in a measure, these untoward symptoms. It was invariably the rule that the urine of patients receiving methylene blue was colored by the drug. Bacteriologic studies of

cases treated by this method showed that the addition of the analin to the other drugs greatly adds to their germicidal power on the gonococcus; this fact was also demonstrated with solutions of methylene blue alone. Of 105 cases of specific urethritis thus treated by Horwitz, 77 were cured within three-weeks' time, 16 required four weeks to complete the cure, and the remaining number recovered within seven weeks. In cases of non-specific urethritis, on the other hand, it was maintained that the employment of methylene blue was of no value.

F. A. Packard, at the last meeting of the Pathological Society of Philadelphia, exhibited several curious specimens of a papillary new growth of the serous surface of the ileum, from a child dead of tuberculous peritonitis. The neoplasms consisted of numerous slender, whitish processes, $\frac{1}{30}$-inch in width and about $\frac{1}{3}$-inch in length, and were distributed over the serous surface of the ileum at the middle of its course; they consisted, microscopically, of collections of loosely formed areolar tissue enveloped with a serous covering, and having a central arterial canal. Inasmuch as the growths conformed to no known histologic type, their exact character could not be determined,

L. J. Hammond, in a paper read before the Obstetrical Society of Philadelphia, at the last meeting of this body, expressed the belief that quinin exercises a decidedly tonic effect upon the propulsive powers of the uterus during labor, particularly in women whose general muscular development is deficient or atonic. He administered the drug to 100 cases of parturient women, giving half-hourly doses of 10 grains until 30 grains had been taken. Of the thirty-eight primiparæ to whom quinin was given, there was an increase in the frequency and force of the uterine contractions in thirty-five cases; of the sixty-two multiparæ, an increase in the propulsive power was noted in thirty-one instances.

By the will of the late George Plumer Smith, who recently died in this city, a large sum of money is left to the Pennsylvania Hospital, and smaller amounts to other city and State charitable institutions. The entire amount left by the late Mr. Smith is nearly three-quarters of a million dollars, of which sum the entire residuary estate, amounting to about $400,000, is bequeathed to the contributors of the Presbyterian Hospital. The sum of $10,000 is also left to the Presbyterian Hospital of this city.

The inquiry into the mental condition of Samuel Henderson, the boy murderer, has been completed by the alienists appointed by the District Attorney, Drs. Chapin and Morton. Contrary to general expectations, the precise nature of their report will, it is announced by the authorities, be withheld from the public until the case comes up for trial, the time for which has not yet been decided upon.

During the week ending February 19th, the number of deaths reported from all causes in this city was 491, or 15 less than reported last week, and 39 less than those of the corresponding week of last year. Of this number, 148 were of children under five years of age. There were 82 new cases of diphtheria reported, with 25 deaths —the same number of cases and of deaths as reported last week; scarlet-fever cases number 57, with 7 deaths from this cause.

OUR BERLIN LETTER.

[From our Special Correspondent.]

THE NEW CHARITÉ AS IT WILL BE WITHIN FIVE YEARS —A PASTEUR INSTITUTE FOR BERLIN AND WHAT IT MEANS AS TO THE TREATMENT OF RABIES—NEW MEDICAL JOURNALS—THE MEDICO-LEGAL DIFFERENTIATION OF DEATH BY FREEZING.

BERLIN, February 17, 1898.

THE last number of the *Charité Annalen* (the report of the principal hospital here in Berlin) contains an interesting account of the early days of the Charité. So much of Berlin medical history is contained in the wards of this old hospital that it will always have a place in medical lore. Virchow, Frerichs, Traube, to say nothing of many others, did their great work here. The most interesting part of this account, however, is the future of the Charité; for at the beginning of the Twentieth Century the University of Berlin will have in the new Charité, just about to be built, one of the largest, most modern, best-appointed, and best-equipped hospitals for teaching purposes in the world. This is the confessed aim of the present administration and the question of money is not to stand in the way.

Those acquainted with the present Charité know how much this is needed. Those who know other hospitals about Berlin, Moabit, Friedrichshain, or the Kaiser and Kaiserin Friedrich Kinderspital in Reinickerdorf, know what a model hospital the modern German institution may be. Special pride is taken in making the new Charité in every way worthy of the medical center of the world, as, of course, every good German (need I say most every one else) considers Berlin to be.

Some 10,000,000 marks ($2,500,000) are to be spent on improvement of the Charité within the next five years. Practically all of the old buildings are to disappear to make room for modern structures. Some of these are already under way. The new Pathological Institute, to cost 1,500,000 marks ($375,000), is nearly completed. It has been a pet project of Professor Virchow's for many years to have the erection of the new institute under his direction before his death. The arrangements of the building will be such that it will surpass any thing in this line so far erected. It is to be hoped that the veteran professor will not say his *nunc dimittis*, until, working for some years in the new laboratories, he has proved how great are the opportunities still left in pathology. The Laboratory of Pharmacology and Toxicology is also well under way. The Department for Mental and Nervous Diseases is soon to be begun. It is a sign of the times and of the amount of attention that is being devoted on all sides to diseases of the nervous system, that, after the Pathological Institute, this department comes next in the amount to be appropriated for its new quarters, 1,200,000 marks ($300,000) will be spent for its construction.

The whole plan of the new institution is on a magnificent scale. Government regulation of universities has its

disadvantages, but where the best interests of education are consulted, as they seem to be here, results may be accomplished which private effort could not attempt. Thanks to the farseeing liberality and generous interest of the government, though calls are made on it from all sides, Berlin is likely to retain the place she has held for the last thirty years as a leader in education, and especially in medicine. With opportunities such as will be afforded in the new clinics and laboratories, still more may be expected of her in the first half of the Twentieth Century, than has been the case in the latter half of the Nineteenth.

One item in the budget of expenses for the Institute of Infectious Diseases here in Berlin for the year 1898 is especially interesting. Four thousand marks ($1000) is appropriated for the establishment, in connection with the Institute, of an experimental station for the treatment of rabies after the method of Pasteur. As yet the work is to be only tentative, it is said, but the change of front after the decided opposition that Pasteur's treatment has always met in Berlin, especially at the hands of Professor Koch and his school, makes the establishment of such a department in the Institute of which he is director a noteworthy and significant departure.

There has been no little uneasiness in many cities of Germany of late over reported cases of hydrophobia. From Hamburg and Dresden, as well as from about Berlin itself, such reports seemed not absolutely without foundation. From Königsberg, Breslau, and other places near the Russian frontier, came reports of cases, in which there could be no doubt that genuine lyssa was at work.

The German medical men who visited the International Medical Congress at Moscow were deeply impressed with the regard the Russians have for the Pasteur method of treating this disease. Their statistics showing its efficacy were freely distributed during the sessions of two or three of the sections. The Rabies Department of the Imperial Institute of Experimental Medicine of St. Petersburg was a striking object lesson. This institution is magnificently arranged, on a scale only second to that of the Pasteur Institute in Paris, if even this much is to be allowed.

Their results of treatment have been most satisfactory, and yet Russia is the hotbed of the most virulent form of rabies, from which probably most of the rabies of Europe comes. The wolves of the Steppes are often infected and give the disease to other animals. At times they attack men too, and their tendency to spring for the face and neck results in the most serious form of rabies. The virus is rapidly absorbed in large quantities, owing to the rich lymphatics of these parts; while the proximity of the point of infection to the nervous centers, in which by preference the virus localizes and reproduces itself, inevitably makes the infection extremely severe. The prognosis of head rabies, that is, the disease developing after a bite in the head region, is universally acknowledged to be particularly bad—yet it is with this class of cases that the tests in Russia were made.

Russian statistics on most things medical, as well as Russian medical and surgical opinions generally, will count for much more in the medical world since the profession has had a chance to see for itself the thoroughly scientific quality of the work being done there. So it has been in this case. Now that Berlin has fallen into line we can confidently look for the establishment of Pasteur departments in most of the medical universities of Germany. The end of the opposition to Pasteur's method is at hand. It is probable that this will lead to a great many changes in opinions in America too, for Americans generally have taken their cue in the matter from the Germans rather than from the English. In England the best opinion has long since declared in favor of the treatment, and in the English Army, in the colonies at least, the bite of an animal thought by a physician or a veterinarian to have rabies, must be followed by the Pasteur treatment, if the affected individual is to retain his connection with the army.

Three new medical journals have seen the light in Germany within the last couple of months. It is an index of the immense number of medical journals that already exist over here, that practically all three of them are to be devoted to the reviewing and abstracting of other medical journals. The *Dermatologisches Centralblatt*, edited by Dr. Max Joseph here in Berlin is one. *The Medicine of the Present*, a sort of medical *Review of Reviews*, also to be issued here in Berlin, is another; while the third, *The Centralblatt für die Grenzgebiete der Medicin und Chirurgie* (Review of the Borderland Lying Between Medicine and Surgery), though edited by Dr. Hermann Schlesinger of Vienna, is published by Fischer of Jena, and is evidently intended to draw subscribers from all over Germany. It is to be a supplementary journal to the *Mittheilungen aus der Grenzgebiete*, etc. (Communications from the Borderland, etc.), edited by Professor Naunyn of Strassburg, and Mikulicz of Breslau, and which, though but a year or two old, is regarded as one of the standard medical journals here in Germany.

When so many *Reviews of Reviews* can find a place, it is no wonder that the disaffection among medical men, as to the volume of periodic literature that is being poured from the press, is on the increase. *Schmidt's Jahrbücher* reviews 170 important contributions to the literature of tabes which have appeared in the course of the last year. Some of them are volumes, many of them almost monographs. It is evident that for the practitioners, a still further degree of potency in the concentration of his medical literature will have to come, and we will ultimately have a *Review of the Reviews of Medical Reviews*.

Recently there have been some interesting contributions to the question of the means of deciding, with some assurance, whether people found dead, seemingly from exposure to cold, have really died from freezing or not. The well-known rose color of the cutaneous surface, which comes on as the result of cold, which paralyzes especially the peripheral vasomotor nerves just before death, is not always present, and may sometimes occur under other conditions. The recent study of that little-known condition, paroxysmal hemoglobinuria, seems to have supplied a new sign of valuable significance. In certain people whose red blood-cells are not quite normal, a great many of them perish when exposed to even slight cold, and hemoglobin appears in the urine. In even perfectly nor-

mal individuals, when exposed too long to severe cold, a certain amount of hemoglobin appears in the urine; so that in people frozen to death, it is claimed, this substance will always be found.

TRANSACTIONS OF FOREIGN SOCIETIES.

Paris.

A THEORY OF GRAVES' DISEASE—PROTARGOL, A NEW SILVER SALT FOR USE IN THE EYE—GASTRIC HEMORRHAGE—BLOOD-LETTING, EMETICS, AND BLISTERS—PERFORATING ULCER OF THE DUODENUM—HOLLOW RENAL CALCULUS—SURGICAL TREATMENT OF ULCER OF THE STOMACH—OPERATION IN UNUNITED FRACTURES—DANGERS OF PICRIC-ACID TREATMENT OF BURNS—ORCHITIS TREATED BY REFRIGERATION.

AT the session of the Academy of Medicine, held January 11th, CORNIL spoke of *a theory of Graves' disease* which presupposes that the general condition which underlies this affection is an arthritism, and that the immediate cause is a thyroid insufficiency. In his opinion there are other conditions capable of preparing the organism for the advent of this disease. Infectious diseases which favor auto-intoxications may produce the conditions favoring the development of exophthalmic-goiter prebasedowic states. In other words, in Basedow's disease there are two intoxications of different origin, one superimposed upon the other. The first is a diathetic intoxication whose principal localization is in the thyroid gland. The second, a result of the first, is the thyroid intoxication properly so-called. In accordance with this theory, treatment should be divided into two parts: the treatment of the general disease, and treatment of a symptomatic nature. The general treatment is hygienic. Symptomatic treatment consists in faradization of the carotid region. If this is frequently repeated there will rapidly follow an improvement in the condition of the patient practically equal to a cure.

DARIER mentioned the use of *a new silver salt in eye troubles—protargol*, which is a combination of protein and silver. This substance is not at all irritating, and besides its bactericidal property it also has the power of penetration, and presents the advantage of not being precipitated in solutions by albuminous material, by sulphids, or by alkalies.

At the meeting of January 18th, DIEULAFOY described *two cases of gastric hemorrhage* so great that in both life was endangered. One of these patients was successfully operated upon, and the blood was found to come from a very superficial ulceration, so slight that it was discovered with difficulty. The lesion was sutured, and there was no return of the hemorrhage. At the autopsy of the patient who was not operated upon, an exactly similar condition of affairs was found. As neither of these erosions had extended beyond the external layer of the mucous membrane, they could not properly be considered as "simple ulcers of the stomach;" though it is possible that they represent the initial stage of that disease. If gastric hemorrhage is slight, one may content himself with medical remedies to control it; but in all hemorrhage which threatens life, recourse should be had to a surgical operation.

HAYEM expressed himself as astonished that any one should counsel operation in these cases, as many patients recover after extensive hemorrhage, under a treatment consisting of absolute rest in bed and a milk diet; to which injection of salt solution may sometimes be added with benefit.

At the session of January 25th, DUPLAY insisted upon the advantage of intravenous injections of large quantities (three pints) of artificial serum in surgical operations accompanied by severe hemorrhage. By this procedure he was able to save a patient upon whom he operated for gastric hemorrhage. In order to find the ulcer, which was upon the posterior surface of the stomach, the entire organ was inverted through an incision in its anterior wall. Marion has reported six similar operations in foreign countries with three deaths from collapse, two of them occurring within a few hours after operation. It is at least possible that these patients might have been saved by injections of saline solution. Gastro-enterostomy offers little hope of controlling the hemorrhage, and is not the operation to be chosen in these cases. The stomach should be widely opened and the ulcer sutured, or if need be, excised.

ROBIN read a paper upon *blood-letting, emetics, and blisters*, and advocated a return to their use. There can be no doubt he said that blood-letting increases respiratory exchanges and determines a superactivity of all the phenomena of nutrition. Emetics have a most powerful action upon the capacity and aeration of the lungs, upon the formation of carbonic-acid gas, and the absorption of oxygen. There is, therefore, a chemic as well as a mechanical reason to justify the use of emetics, especially in the treatment of bronchial affections. Repeated examination of patients treated by blisters has shown that the absorption of oxygen is increased by their use. This is apparently due to the fact that in a given time more air is drawn into the lungs.

At the session of the Surgical Society, held January 5th, SCHWARTZ referred to four cases of *perforating ulcer of the duodenum*, in three of which surgical relief was attempted. Unfortunately all four patients died. The diagnosis of peritonitis due to perforation of duodenal ulcers is often extremely difficult. The most likely errors are those of intestinal obstruction and peritonitis due to appendicitis. In a recent collection of twenty-three cases, it is noticed that seventeen mistakes of this character were made in diagnosis. The presence of absolute constipation and the absence of gas, as a result of paresis of the intestines, exists in cases of peritoneal septicemia, and the surgeon who has made a diagnosis of intestinal occulsion often closes the abdomen without having found anything whatever, and only at the autopsy is the condition revealed. The results of operation are not brilliant. In the twenty-three patients referred to, only three were cured. It is to be noted, however, that only five of these operations were performed in the first twenty-fours after the outset of symptoms, two of the cures which resulted being among these five cases.

ROUTIER and HARTMANN mentioned instances in which they had failed to find the seat of the trouble, but had drained the abdomen. In both cases there was temporary improvement, life being prolonged for some days, but a permanent cure did not result.

TUFFIER reported a rare form of *hollow calculus of the kidney* found at autopsy upon the body of a man aged sixty-three years. Sections of the calculus showed that the inner layers were the most recent. Such a calculus apparently begins in an incrustation of the lining of the pelvis of the kidney.

At the session of January 12th, CHAPUT spoke of the *surgical treatment of ulcer of the stomach*. He mentioned five instances in which he had operated for ulcer of the stomach, with four recoveries. Two of the ulcers were of a carcinomatous nature. Twice he performed a gastro-enterostomy, twice a gastro-enterostomy combined with an entero-anastomosis, and once a pylorectomy. The one fatal case was complicated with an abscess of the pancreas. Chaput considered intestinal anastomosis an indispensible accompaniment of gastro-enterostomy. He preferred the retrocolic method.

PICQUE mentioned the value of *Hueter's sign* in deciding upon operation in *ununited fracture*. This sign is the lack of transmission of osseous vibration, noticeable when there is interposition of muscular fissues between the ends of the fractioned bone. BERGER said that one ought not to wait more than fifteen days in such cases, and that if extension for that length of time does not result in union, operation is indicated. HENNEQUIN mentioned the fact that in very oblique fractures there might be absence of crepitus, without muscular interposition. The same might be true in transverse fractures, when periosteum had slipped in between the bones.

At the session of January 19th, WALTHER spoke of the *treatment of burns by picric acid*. It is too little known that this remedy may produce in children symptoms of acute poisoning; moreover, it frequently causes so much pain that its use has to be abandoned.

BRUN had seen a child of eighteen months die with vomiting, diarrhea, and a yellow color of the skin, which followed the treatment of burns of the leg with picric acid.

REYNIER said that picric acid may be used with benefit in superficial burns, as it often instantly relieves the pain. In deep burns, however, its use is contraindicated.

At the session of the Therapeutical Society, January 12th, DU CASTEL stated stated that the instances in which it is *necessary to treat in bed patients suffering from orchitis* are very rare. He further mentioned the fact that an antiphlogistic treatment of this affection is both useless and dangerous. As long ago as 1888, Diday showed that the application of ice gave great relief. Acting on this suggestion, Du Castel makes a superficial application of chlorid of methyl to the scrotum on the affected side, covers it with a light layer of cotton, and allows the patient to go about wearing a suspensory bandage. Refrigeration may also be performed with chlorid of ethyl if the chlorid of methyl is not obtainable. This treatment has given good results, not only in uncomplicated cases, but also in those in which there is an associated inflammation of the tunica vaginalis. There are certain rebellious cases which will not respond to any remedies, but they, too, do as well under this method of treatment as under any other.

SOCIETY PROCEEDINGS.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting, Held January 19, 1898.

THE President, L. DUNCAN BULKLEY, M.D., in the Chair.

DR. JOSEPH COLLINS read the paper of the evening, entitled

THE TREATMENT OF DELIRIUM. (See page 257.)

DISCUSSION.

DR. ROBERT A. MURRAY: There is one point upon which the author has not touched, and that is the difference in patients in their liability or non-liability to delirium. That some persons have a tendency to delirium is as well known as is the fact that some are more susceptible to the action of mydriatics and narcotics than are others. This is one of the things which most strikes the physician, especially in the treatment of children. The author's classification is certainly very good as a basis for therapy. In regard to baths, the warm bath has a better effect in most cases than the cold. Many of these patients, particularly women, are very restless, and a warm bath seems to better quiet the nervousness. The point which the author has made with reference to the proportionate relation of fever to delirium is well taken; but there is, however, a delirium which is dependent upon fever and which disappears when the temperature goes down. What has been said against the use of bromids in delirium is also good; for most physicians who occasionally see such cases in general practice seem to think that depressants are indicated, especially in alcoholic delirium. The treatment employed by the late Dr. Alonzo Clark, who gave the latter class of patients plenty of infusion of wormwood, put them in a padded cell, and watched the pulse, was not far out of the way. Much may be accomplished without the use of hypnotics, although necessity sometimes compels their administration. In such cases sulfonal is better than trional. In the delirium of pneumonia phenacetin with caffein and codein has a good effect. The author's mention of the delirium of chorea brings to mind the delirium of rheumatism; for there is a delirium of rheumatism, and it very much resembles that which occurs in uremia. In these cases, when the temperature is high, the cool bath gives excellent results. There is also a delirium which is due to pain. As a rule, however, delirium is caused by poisoning due to the retention in the system of effete matter or to the entrance of extraneous poison.

DR. B. F. CURTIS: The paper is so exhaustive that it leaves but little to be added, except perhaps from a sur-

gical standpoint. The treatment of surgical delirium is generally a rather simple affair. It is usually due to septic infection and its accompanying fever, and is treated by the removal of the cause—sepsis. In the asthenic and typhoid forms of delirium treatment is of but little avail. Another form is that due to intoxication by iodoform, and it is hardly necessary to say that great care should be exercised in the use of this drug. In cases in which there is an extensive wound which has been dressed with iodoform, and delirium occurs, the dressing should be immediately removed. It is especially necessary to be on the watch for these symptoms in cases in which the patient is old.

This form of delirium is particularly likely to be manifested at night or when there is any rise of temperature. In such cases the mental state may remain perturbed and the patient practically insane for a time, and perhaps permanently so. In a case recently seen, that of a man sixty years of age, who had been operated upon for a very extensive tumor of the jaw, iodoform poisoning developed, and although every other condition cleared up, the dementia remained. As a rule, however, the delirium of senility is the easiest of all to treat. In surgical cases in the aged, if the patient is in fair health, the mind will generally remain clear if the bed is left as soon as possible and if nutrition is maintained. Stimulants are indicated, especially milk punches, which should be given at night during the fasting hours. In jaw cases, and these are often in old people, it is very necessary to get the patients out of bed as soon as possible. This may be done on the third or fourth day, even after removal of the upper jaw, unless there is much exhaustion from hemorrhage.

In regard to the delirium accompanying head injuries, I recently operated upon a patient for epilepsy in whom there was a cystic clot in the brain. The skull had been fractured five years before, and had been trephined at that time, a considerable amount of bone being removed leaving a gap in the skull the size of a silver quarter. The patient had also lost a good deal of brain substance, and there was present a left hemiplegia, which dated from the time of injury. Epilepsy had slowly developed, the spasms beginning on the left side, chiefly in the arm. Operation showed that the superficial part of the brain, just below the fissure of Rolando, was converted into loose cellular tissue containing serum in small cystic cavities, and the epilepsy had apparently been caused by its presence. Dr. Hammond, who was present at the operation, thought it would be best to remove all this cicatricial tissue, and this was done. The patient made a good recovery from the operation, although during the first twenty-four hours he had three very severe epileptic attacks. He was given sodium bromid, gr. xxv, three times daily. On the second day after the operation the temperature rose to 101° F., although the condition of the wound was aseptic. The temperature came rapidly down, and the drainage-tube was removed. About a week after the operation he began to act strangely, being excited and difficult to control, and the temperature began to rise. He complained of a great deal of headache and of pain in the paralyzed side. The paralysis had not been increased by the operation, which did not, however, involve any of the motor centers. During the following two weeks the condition became worse, and the temperature was so high that I determined to reopen the wound. This was done, the incision being made to the depth of about an inch, and a small quantity (about half a dram) of broken-down tissue evacuated and a drainage-tube introduced. The temperature then went down and the patient became more manageable. The scalp has since fallen in where the bone was removed.

The most interesting feature in this case is that the temperature and the delirium did not seem to go together. The delirium was apparently an independent condition. It is also difficult to account for the temperature with the low degree of infection present; yet this would seem to have been the cause of the rise of temperature, for when the wound was reopened there was a cessation of the symptoms. In my experience, head injuries in which there is delirium are always accompanied by a septic condition. The temperature in these cases is a very poor guide to the presence of a septic condition, however.

DR. G. M. HAMMOND: I am very much pleased with Dr. Collins' paper. I do not think any of us will take issue with him in the main conclusions which he has reached. The principal thing is to induce sleep and maintain nutrition. I would like, however, to say a word of caution in regard to the use of sulfonal in these cases. Large quantities of it are required to produce sleep, and, if there is any degeneracy of the cardiac muscle, a serious result is apt to follow. Particularly is this likely to be the case in senile patients, in Bright's disease, and in typhoid fever. In a case of alcoholism I once gave 40 grains of sulfonal, and in thirty minutes the patient was in a state of collapse, and it was with difficulty that he was revived. I have also used chloral a number of times, particularly in alcoholic cases, and have never observed any unpleasant effects. I much prefer it to the other hypnotics. One point which the author mentioned but did not sufficiently emphasize is that these remedies are not given to patients to cure them, but to keep them quiet. This is sometimes necessary, although I strongly deprecate the practice of giving hypnotics to the nurse to be given to the patient as she may think necessary. I have known a nurse to give a patient as much as 1/15 of a grain of hyoscyamin to induce rest, thus rendering the patient unconscious for hours. This is a very dangerous practice, and, of course, should be depreciated.

I think I can agree with the previous speakers in regard to the use of the hot bath, for I have seen many cases in which it seemed preferable to the cold. It is much more grateful to the patient, particularly in rheumatic cases. The cold bath is probably more efficacious in a typhoid condition.

DR. S. H. DESSAU: I certainly concur in what has been said by the author. The paper is a most instructive one to the general practitioner, and the subject of classification has been handled in a masterly manner. The only point upon which I can add anything is that in regard to the delirium of pneumonia. The details which

the author has given us in regard to this show that the most serious form occurs in the streptococcic variety of pneumonia. I have found that in a certain number of cases occurring in children delirium occurs at the onset of the affection, especially when the apex of the lung is involved. In regard to the use of baths or the cold pack in the treatment of delirium of scarlet fever, this treatment has been approved by those who have had a wide experience in these cases. The temperature and the delirium seem to be so closely associated that it is difficult to think that the one is not dependent upon the other, although the author claims that the two conditions are entirely independent.

I have certainly been enlightened in regard to primary delirium due to parenchymatous encephalitis. Some years ago, before the present method of treating delirium was in vogue, I was called to see a robust young man who was in a most violent delirium. He had not been long in this condition, nor had he been using alcoholic liquors to excess. The temperature was 105° F. At that time veratrum viride was being used a great deal, and I thought I would try it. A young medical student living in the same house agreed to take care of the patient, and I gave him the remedy; to be guided in its administration entirely by the condition of the pulse, which was very full, bounding, and beating at the rate of 120 or 130 per minute. I left directions that the patient should be given a drop of the tincture of veratrum viride every hour until the pulse was brought down to 80. He was so violent that it required three men to hold him in bed. The treatment was carried out very carefully, and the next morning when I called he was asleep. Nothing was given but the veratrum viride, and it brought down the pulse and temperature and stopped the delirium.

DR. R. C. M. PAGE: In regard to the delirium of typhoid fever and pneumonia, it has been claimed by Bouchard, Epine, and others, that it is caused by impaired digestion, followed by the formation of ptomains and a corresponding auto-intoxication. It seems to me that it is more dependent upon a weak heart and a diminished volume of blood with anemia of the brain. Many of these cases are relieved by proper stimulation, although I do not think that this stimulation acts as an antidote to the ptomain poison, but rather keeps up the heart and nourishes the brain beyond the point at which delirium is produced.

DR. J. RIDDLE GOFFE: The author has included the diseases and pathologic conditions in which delirium occurs in a masterly sweep which we can but admire. It is rather unusual for a symptom to be taken as the chief topic of a discussion; still, the interest which has been aroused by the subject in its various phases justifies the importance which has been given to it. My experience with delirium has been almost exclusively confined to puerperal and surgical cases, and treatment has been stimulation of the heart and attention to the bowels. In septic conditions following laparotomy the treatment has been the same. I have quite extensively used phenacetin, combined with codein and alcohol, in these cases, and with good results. I have had three cases in which iodoform poisoning occurred, accompanied by a low, muttering delirium. I have employed no special treatment except to prevent further absorption. One of the cases, however, fell a victim several weeks later to the most aggravated attack of jaundice I ever saw. It is, of course, a question whether this could in any way be attributed to the iodoform poisoning.

DR. SIMON BARUCH: I regret that I did not hear all of the paper. I may say, however, that I am in accord with much the author has said, and especially would I emphasize the fact which he feared would not be accepted by the general practitioner, *i.e.*, the frequent lack of relationship between hyperpyrexia and delirium. There is no doubt in my mind that the two are usually independent of each other, especially in typhoid fever. The best proof of this is that at present I never see delirium in this disease in private practice, because I have the patient bathed by the Brand method from the fourth or fifth day—in suspicious cases—even before the diagnosis is made, whereas fifteen or twenty years ago, before I began bathing my patients, delirium was constantly a symptom, and I often find it present in hospital cases which are first seen late in the course of the disease. It has been claimed that the cold bath prevents delirium by reducing the temperature. I have always combated the boasted antithermic agency of the cold bath. While reduction of temperature is incidently produced by it, it is the best agent we can employ because it counteracts the manifestations of toxemia, improves the impaired action of the heart, and is, therefore, the most reliable cardiac tonic we have when properly used. It reduces the temperature by favoring oxidation and elimination of toxic products, which are the essential factors in causing delirium, and enhances digestion and appetite. I cannot agree with the author that the delirium which occurs in the later stages of typhoid is due to exhaustion. In most cases I think it is the result of sepsis from local infection.

In the delirium occurring in the early stages of scarlet fever (sometimes without much rise of temperature) the best way to give the bath is to submerge the patient, then repeatedly and rapidly remove him from the bath, or a child may be placed in an empty tub, or one in which there is a little warm water, and one or more affusions over the back, chest, and head may be given, followed by very gentle rubbing, after which the child may be put to bed. This may be repeated every two hours; or a full bath at 85° F. reduced to 70° F. may be given for a few minutes. The same treatment can be employed with advantage in typhoid fever when the temperature is below 102° F., in cases in which there is delirium.

In delirium tremens I think powerful hypnotics and anodynes are contraindicated; hence, I always avoid them. In such cases attention to nutrition is the principal indication.

DR. COLLINS, in closing: The points which have been raised, with the exception of that made by Dr. Jacobus, are well taken. Dr. Curtis said that when delirium occurs after an operation upon the cranium, he feels sure

that there is septic infection. I presume this conclusion is based upon personal experience. I do not think that in many of the cases in which there is delirium following surgical operations that it is necessarily dependent upon the temperature.

I am much gratified by Dr. Amidon's remarks, but perhaps I shall be allowed to say that I am not so wedded to the use of sulfonal and trional that I cannot be divorced from them. They are agents which are less apt to do harm in the hands of the general practitioner than is chloral. Personally, I have had no disagreeable experience with chloral, but I know that the effect of its repeated use is hemolytic. It very rapidly destroys the red blood-corpuscles and produces profound anemia.

As to Dr. Jacobus' statement in regard to sunstroke, it should be said that in some cases of insolation there is no rise of temperature. Sunstroke has been proved to be dependent upon an acute intoxication, probably autotoxic, which causes in turn a parenchymatous encephalitis. I have now under treatment two cases of disseminated sclerosis which began last August as cases of sunstroke. In other words, the lesion in the beginning was acute disseminated encephalitis, the foci of which have undergone transformation into sclerosis. Van Gieson has shown that in some instances, if not in all, sunstroke is an acute toxemia. The poison acts upon the heat centers and produces fever. It acts upon the intellectual areas to produce delirium. It is faulty logic to say that the delirium is dependent upon the fever. Dr. Fruitnight has cited some examples of the widespread and deep-seated impression that flightiness is due to to febrility, but I agree with him in denying it.

In regard to delirium tremens, it has seemed to me that physical restraint contributes to the great mortality. The most potent way of producing alcoholic pneumonia is by the use of the captive-sheet made fast across the patient's chest. I place two attendants in charge of such patients, and order ⅛-grain calomel triturates every hour with a view to clearing out the intestinal tract. I do not often use sedatives, and can only repeat what has been said in the paper that it is a pernicious habit to give chloral and the bromids as a routine practice, and follow it up by digitalis to counteract the depressant effect which they produce. When the alimentary tract is in a condition to receive food and absorb it, recovery will ensue if attention is directed to alimentation alone. Naturally, I do not mean to say that oftentimes chloral and the bromids are not the most useful measures at our command, but they should be given cautiously. I am very much opposed to the hot bath in delirium tremens, for I have seen much depression and even collapse follow in cases in which there was an asthenic condition. In such cases the warm pack is better, for it is not followed by a depressant effect.

I have been gratified to hear Dr. Baruch's remarks, but I cannot agree with him in what he has said about typhoid fever, although I am well aware that to disagree with him on any point connected with the treatment of this disease must seem presumptuous. I believe that at the end of the third week of typhoid fever there is an asthenic general condition and an immune state of the blood which does not lend itself to the further absorption of toxic products, whether septic or pathogenic. I believe, moreover, that the clinical manifestations are in entire accord with this statement. There are no evidences of infection at this stage, and I believe that the delirium which occurs is the delirium of exhaustion.

HARVARD MEDICAL SOCIETY OF NEW YORK.

Stated Meeting, Held December 18, 1897.

THE President, JOHN WINTERS BRANNAN, M.D., in the Chair.

DR. JOSEPH A. KENEFICK read the paper of the evening, entitled

SOME MANIFESTATIONS OF SYPHILIS IN THE UPPER RESPIRATORY TRACT. (See page 266.)

DISCUSSION.

DR. EUGENE FULLER: The author has said that late manifestations of syphilis of the respiratory tract are especially liable to occur in those patients who have not received careful treatment during the early stages of the disease, and this is true, still there are cases in which individuals have taken extremely good care of themselves and yet have had very troublesome late manifestations of syphilis. I have in mind a man whom I saw for the first time seven years ago, and who, during five years, religiously followed the treatment ordered, but he had on two occasions relapsing gummatous lesions which required the most heroic treatment.

In regard to the removal of bone in cases of syphilis of the air passages, I understood the author to say that he would be conservative in this particular, especially in cases in which there is necrosis of the turbinates, etc. I fully agree with him in this. It is much the better treatment not to interfere with bony structures. The diseased bone will come away of itself if left alone, and in this way there will result less loss of tissue than if operation were attempted. A patient of mine with necrosis of the jaw has been very persistent in his request that an operation be performed. This, however, I refused to do, and now the bone has become sequestrated and only a small piece of it is coming away.

The subject of syphilis in connection with disease of the kidney is most interesting, but it is a question whether the mercury does the damage to the kidney or whether it is caused by the early syphilis. It has practically been decided that the latter theory is correct.

As far as stomatitis is concerned, it is best to persist in the administration of the mercury, and at the same time keep the mouth as clean as possible. For the latter purpose peroxid of hydrogen is very efficient as a mouth-wash.

DR. HOWARD LILIENTHAL: I have been particularly interested in the statement made by the author that the fact that a lesion rapidly resolves under antisyphilitic treatment does not necessarily prove that it is a syphilitic lesion. This is a point not often taken. In regard to operative treatment, I think that in cases in which there is circumscribed ulceration about the tongue, for instance, which does not respond to antisyphilitic treatment, op-

erative measures should be considered, and enough of the ulcer removed to permit microscopic examination.

Stomatitis should always be forestalled by the most rigorous care of the mouth and gums. I direct the patient to use a tooth-brush and a mouth-wash at least every three hours, and as a result I have not found it necessary to discontinue the treatment on account of stomatitis in cases in which this rule has been carried out. I have, however, observed cases in which salivation has occurred from neglect of the mouth, or in which the patient has been taking mercury on his own responsibility. In such cases the use of the remedy must be discontinued or the patient's general health will suffer.

DR. F. R. STURGIS: The author has spoken of the late appearance of secondary lesions. It is well to bear in mind that in the text-books the division of syphilis into stages is very misleading. Such secondary lesions as mucous patches, chronic and stubborn to treatment, often appear several years after the initial symptoms, and in some cases there is complete destruction of the hard and soft palates even during the first six months of the disease. This was the case in a patient of mine who was tuberculous, and who took the iodids very badly. His lesions were severe, and from the first were attended by ulceration. He died within a year. Late lesions are usually attended by destructive breaking down. The lesions of the nervous system which occur in the early stages are not, as a rule, as severe as when they appear late, nor are they as rebellious to treatment.

As to the question of whether treatment will prevent the development of late symptoms, I agree with Dr. Fuller, and believe that the best safe-guard is thorough treatment, although this does not always have the desired effect. It is here that the question of intermittent treatment must be considered. Mercury, when first given, acts as a stimulant and later as a depressant; if it is administered during a long period, the patient loses flesh and the red blood-corpuscles diminish in number. These symptoms are an indication for stopping the treatment. I believe, however, that a thorough course of mercury or iodid will usually place the patient in the best condition to withstand the late symptoms.

With regard to the kidneys, I also agree with Dr. Fuller. I am loath to believe that mercury properly administered ever produces disease of the kidneys. When lesions of this kind occur I believe that they are due to the syphilis and not to the mercury.

So far as the relative merits of mercury and iodid are concerned, I regard mercury as the right bower and the iodids as the left. The latter are useful on account of their rapid action in checking ulceration. In the early lesions the iodids are not of much service except as a tonic. I would confine the use of the iodids to those cases in which rapid therapeutic effect is desired, when there is loss of tissue, and especially in cases of syphilis of the nervous system. In these it should be given to the point of tolerance—until toxic effects are produced or the symptoms checked.

I also believe that the less we interfere surgically with a syphilitic lesion the better.

I am convinced that many cases of lupus reported as cured by the iodids are late manifestations of syphilis. Lupus invades cartilage and not bone; therefore, when there is ulceration of bone, the disease is syphilis. Given a lesion the nature of which is doubtful, and which is relieved by the iodids, I should be inclined to believe it syphilitic.

DR. CHARLES L. GIBSON: I would like to emphasize very strongly what Dr. Lilienthal has said in regard to the care of the mouth during the administration of mercury. I have always considered most severe those cases in which there are lesions of the upper air-passages. Patients presenting these lesions do not tolerate treatment well, consequently its effect is less marked. In some instances the hypodermic method of administering mercury is indicated. This method is especially applicable in the more severe cases.

In regard to the treatment of syphilitic bone lesions, I am not very familiar with such manifestations in the upper air-passages, but in regard to syphilis of the bones elsewhere in the body, I think that constitutional treatment is very limited in its effect. In such cases the treatment should be pushed as far as possible, and, when it is noticed that there is no further improvement, operation should be considered. I have had several cases in which operation has produced a wonderful effect after constitutional treatment had ceased to be of benefit.

DR. STURGIS: It has been noticed at the City Hospital that on Saturday and Sunday the mouths of syphilitic patients are always more tender, and I am convinced that this is due to the fact that they eat salt fish on Friday. The mouth symptoms are always more marked in salt-eaters. I am inclined to think that the salt is acted upon by the mercury and forms a bichlorid of this metal.

In regard to the treatment of bone lesions, it should always be remembered that the necrosis extends to the original limits of the ostitis, whether the process is located in the nose or elsewhere. My experience has been that interference aggravates the affection, so I am exceedingly cautious about meddling with necrosed bone in syphilitic subjects.

DR. FULLER: In regard to the question of the treatment of syphilitic bone-lesions, I do not think that the rule of non-interference holds good in cases in which the leg is involved. It has been said that these bone-lesions should be left alone and that repair will go on when the syphilitic element has been eliminated. When the tibia or fibula is involved, however, I think that the blood pressure caused by the patient walking about will prevent repair even when the syphilitic element has disappeared.

The question of the hypodermic injection of mercury is a very interesting one. I have employed for this purpose a solution of 1½ grains of salicylate of mercury to 30 minims of benzoinol. The injection should be made into the buttock, and care should be exercised in order to avoid introducing bubbles of air, otherwise severe pain will result. The first injection is apt to be more painful than subsequent ones. This treatment I have noticed on rare occasions to be followed by a fit of coughing which resembles the paroxysms of whooping-cough. Occasion-

ally a mercurial diarrhea will result. A strong mercurial odor of the breath will be noticed in cases in which the toleration point of the drug has been reached. This latter sign is a good test as regards further hypodermic medication, as such treatment should not be repeated while this odor persists.

Dr. Kenefick: In regard to the effect of mercury upon the kidneys, it is important that precautions be taken in every case to avoid overtaxing these organs.

One of the things to be considered in dealing with syphilis of the bone is the fact that the necrotic process begins at the point of bony and cartilaginous union. I quite agree with Dr. Fuller in regard to the advisibility of non-interference with bone-lesions, except under certain conditions. In cases in which there is prolonged suppuration, in those especially accompanied by the many disagreeable features due to the presence of dead bone, the patient will often be glad to submit to operation.

REVIEWS.

The Origin of Disease. By Arthur V. Meigs, M.D., Physician to the Pennsylvania Hospital. Pp. 229. Philadelphia: J. B. Lippincott Company, 1897.

This work, which is devoted especially to disease resulting from intrinsic as opposed to extrinsic causes, is based upon various papers published by the author during recent years, later elaborated and brought together in a volume which appeals to every thoughtful physician. When we read in the preface that "specialism therefore has gone sufficiently far, if not already too far, in medicine, and it is time that something be done to connect the various disjointed threads of knowledge, the true value of which can never be known until they are woven into a complete whole," we appreciate the effort which he has made to bring nearer together pathology and clinical medicine, and congratulate him upon his successful result.

After chapters devoted to an introduction, diseases of age, and origin of disease, there follow those presenting various conditions found in the blood-vessels, heart, lungs, liver, spleen, stomach, intestines, kidneys, and spinal cord. Not only is the text describing these excellent, but 137 original illustrations, drawn to scale and etched directly from the reflection by the camera lucida, give an accurate and at the same time vivid presentation of the tissues under consideration. No adequate synopsis of this book can be given within the compass of a review, but this much may be said: the course of disease is not to be sought for in a single organ, but rather in the involvement of many organs and tissues; many changes usually located in tissues are really dependent upon changes in blood-vessels; the essential condition in many apparently diverse pathologic results is practically one and the same; and finally the old terms, for example, Bright's disease, do not satisfy the present concept of the advanced internalist.

So while we are advancing in knowledge and finding that a broad interpretation of the results of microscopic research as given by the clinician adds to the sense of security with which he reaches his diagnosis, it is perfectly evident that this book will afford little satisfaction to those whose field of view is bounded by the edge of a cover-glass. As an example: "So far as concerns human beings, there is no existing evidence, either clinical or experimental, which can, when judicially examined, be considered to show that consumption is infectious" (p. 28). Again: "Since it has been proven that cases of consumption do result from inflammation, and since at the same time it has not been scientifically demonstrated that the bacillus tuberculosis ever is its cause in human beings, but only that the bacillus is present in the altered tissues of persons suffering with the disease, it is much more logical to believe that consumption is only the result of ill-ordered growth and disintegration of the natural component parts of the organism" (p. 29). To this the pseudo-scientific hirelings of health boards will dissent and professional alarmists will continue to disturb the public for their own private ends. Among practical matters we may cite that compensatory hypertrophy of the heart, as ordinarily described and understood, has no existence; such hearts are degenerated and weakened (p. 84). Amyloid deposit is only a form of fibrous tissue in which there are few nuclei and great quantities of structureless substance (p. 150). The so-called new bile-ducts, the formation of which is the most pronounced feature of Charcot's hypertrophic cirrhosis of the liver, are not bile-ducts, but an early stage of cystic disease (pp. 109. 110). The three remaining chapters treat of the diagnosis, prognosis, and treatment of chronic disease, and are suggestive rather than specific, as, indeed, their brevity necessitates. In the last a change of the habit of the body, as the author expresses it, is believed to be of the most importance. We have read this book with unusual interest because it is instructive throughout, not in any narrow hemmed-in field, but in the broad domain of internal medicine. It bears intrinsic evidence that it is the work of an educated and accomplished physician, who is not only a student and careful observer, but a philosopher as well. The single criticism which we would make is in reference to "fragmentation" of heart muscle (p 80), concerning which some recent work might have been reviewed. The dedication of this book is to Bright, Gull, and Sutton, who have added so much to knowledge in laying foundations upon which others have raised a substantial superstructure. Of this the author has given us a satisfactory and comprehensive view in a volume which is a credit to American medicine.

Genito-Urinary Surgery and Venereal Diseases. By J. William White, M.D., Professor of Clinical Surgery, University of Pennsylvania, and Edward Martin, M.D., Clinical Professor of Genito-Urinary Diseases, University of Pennsylvania. Two hundred and forty-three engravings and seven colored plates. Philadelphia: Lippincott & Co.

This work, which consists of over 1000 pages, is devoted to venereal diseases, syphilis, and the diseases of

the genito-urinary and sexual organs. The authors have endeavored to cover a very large field, and in making such an attempt have omitted much in the way of detail and description that is of great value to the physician and student as well. In several instances, anatomic and pathologic considerations are too briefly dealt with, and the omission of foot-notes, containing useful references and giving due credit to the authorities quoted in the text, is a great mistake in a book of such pretensions. The views expressed throughout the work in regard to this class of diseases are, with certain exceptions, in accord with those held by many authorities. We regret to see much diffuseness of statement and want of lucidity, as an example of which the following astonishing assertion is made: "In chronic anterior urethritis the urethrometers or acorn bougies will show in old cases certain points of lessened dilatability. There will be no other symptoms, while in chronic posterior urethritis there are often tenesmus, prostatorrhea, frequent micturition, spermatorrhea, sexual irritation, increased desire, frequent pollutions, precipitate, often painful ejaculation, feeble erection, impotence, and neurasthenia." Such a conglomeration of varied symptoms as the above, strung together without any attempt at explanation or classification, is wholly unwarranted in a work which professes to be authoritative and scientific. In speaking of the treatment of chronic anterior urethritis, the authors say that "usually the meatus is found to be narrowed," and they advise meatotomy and the passage of full-sized sounds every few days. Such a broad statement as this, made without reserve, is highly dangerous, and if followed as routine treatment will lead to much discomfort and misery for the patient. Meatotomy is a valuable operation in selected cases, but its routine performance must be condemned as bad surgery. In describing external urethrotomy Souley's operation is not mentioned, and although his tunnel catheters, sounds, and filiforms are described and depicted, he is not even credited for their invention; this is an unfortunate omission, considering Souley's valuable contributions to genito-urinary surgery. Three lines are devoted to the treatment of stricture by electrolysis, and the work of Professor Fort of Paris is not even mentioned. Oversight of this kind renders the work of little value as a book of reference. Gonorrheal rheumatism has barely three pages allotted to it, and in speaking of its treatment no mention whatever is made of local urethral medication. This subject, therefore, cannot be considered up to date, and will not be of any aid to the physician who is treating such cases. In the treatment of chancroid, cauterization is given too prominent a place; the authors mention other methods, but say that "immediate and complete destruction of the chancroidal ulcer is the safest routine treatment," and recommend the actual cautery as the best instrument for the purpose. Such painful and routine treatment is not usually indicated in these days of antiseptic dressings and irrigations. Six very unsatisfactory chapters are devoted to syphilis, which is described at length, but it seems strange that the authors did not use their own cases to illustrate the text, as so many of the cuts they have employed, the colored ones especially, are far from good. Many of the chapters on genito-urinary surgery are very good, and one regrets that the authors did not confine their work to these subjects instead of padding it with desultory descriptions of syphilis and venereal diseases. The book is well gotten up, being clearly printed on good paper, but the illustrations are not, as a rule, up to the standard.

THERAPEUTIC HINTS.

For Pruritus Ani.—

℞ Sod. hyposulph. . . . . ℥i
Ac. carbolici . . . . . ʒi ℈i
Glycerini . . . . . ʒv
Aquæ dest. . . . q. s. ad. Oi.
M. Sig. Apply on compresses to the anus.

For Favus of the Nail.—LEISTIKOW advises spraying the part with an ethereal solution of pyrogallol, and the subsequent application of the following mixture:

℞ Pyrogallol . . . . gr. xxiv
β naphthol . . . . gr. xxxii
Hydrarg. ammon. . . . gr. xv
Tinct. guaiaci . . . . ℥i.
M. Sig. External use. Apply by means of a brush.

For Herpes Labialis.—Tincture of capsicum is highly recommended as an efficient early application.

To Remove Freckles.—

℞ Nitrobenzene . . . . gr. xv
Naphthalin . . . . gr. lxxx
Milk of almonds . . . . ℥v.
M. Sig. External use.

For Sciatica.—

℞ Sol. nitroglycerin (1 per cent.) . . ʒss
Tinct. capsici . . . . ʒiss
Aq. menth. pip. . . . . ʒiii.
M. Sig. Five drops three times daily in a small quantity of water; then increase to ten drops three times daily.—*Troussevitch.*

For Irritable Bladder.—

℞ Salol, Tinct. hyoscyami aa . . . ʒii
Inf. buchu. . . . q. s. ad. ℥vi.
M. Sig. One tablespoonful three times daily.

For Follicular Tonsillitis.—

℞ Creosote . . . . . gtt. viii
Tinct. myrrhæ, Glycerini aa . . . ℥ii
Aq. . . . . q. s. ad. ℥viii.
M. Sig. To be used as a gargle every two hours.

For Seborrhea of the Scalp.—

℞ Captol, Chloralis hydratis, Acidi tartarici aa . . . gr. xv
Ol. ricini . . . . . *m.* viii
Spiritus . . . . . ℥iii
Ol. rosæ . . . . . q. s.
M. Sig. Rub lightly into the scalp with the hand.—*Eichhoff.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXII. NEW YORK, SATURDAY, MARCH 5, 1898. NO. 10.

ORIGINAL ARTICLES.

NOTES ON APPENDICITIS, WITH REPORT OF INTERESTING CASES.

BY JOSEPH D. BRYANT, M.D.,
OF NEW YORK;
PROFESSOR OF THE PRACTICE OF SURGERY AND OF OPERATIVE AND CLINICAL SURGERY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

THE uncertainty of things at their best, emphasized by the fact that the hidden manifestations of disease so seldom present harmonious and easily comprehended features, even to those of much experience, leads me to sketch a limited number of unusual cases of appendicitis. While I am not disposed to question the assertion of those who say that appendicitis can be diagnosed with reliable certainty, still I do express the opinion that often its non-existence cannot be known without the aid of operation, and sometimes not even then, until determined by microscopic examination. At first, attention is directed to a class of cases of chronic appendicitis, characterized by abundant and often enormous fibrinous exudation. Five only of this class of cases will be cited now; those that are most indelibly fixed in my mind.

A few years ago a patient was referred to me with a history of repeated attacks of acute pain in the right side of the abdomen, attended with rapid increase of temperature, inguinal tenderness, and the presence of a tumor at the point mentioned. At the time of observation a large, irregular, and immovable tumor was present in the iliac fossa, characterized by moderate tenderness and marked induration. The tumor had been present for several months, and had increased in size and tenderness after each succeeding acute attack, slowly resuming, however, somewhat smaller dimensions during the intervals. Chronic appendicitis had been suspected, in which I concurred, and an operation was advised in the event of another attack. Subsequently the operation was performed by Dr. Mitchell of Providence, and a large mass of induration was found below the cecum, into which an opening was made in the unsuccessful search for the appendix. Finally, the wound was lightly packed with gauze. It rapidly healed, and the induration entirely disappeared. No further trouble occurred during the year or so that the patient remained under the observation of Dr. Mitchell.

The second case of this nature coming to my notice was treated by me in the search for the appendix in a similar manner, and with similar results in all respects.

In the third case, not only was there an enormous amount of long-standing induration, but also local and constitutional evidences of recent suppuration. A free incision was made into the abscess, pus evacuated, and the abscess cavity lightly packed with gauze. It was advised in this case, for good reasons, that the appendix be removed by an independent operation as soon as the induration had disappeared, which was accordingly done with entire success.

The most interesting case of this series came under observation last winter. The patient was a male, an artisan, about thirty years of age, who had a fair physique, and had enjoyed good health aside from the affection under consideration. He did not present a history of specific disease. About six months previously the patient had undergone an exploratory operation upon a large, indurated tumor of uncertain character, located in the right inguinal region. It was thought that it might contain an appendical abscess. On exposure of the tumor it was regarded as an inoperable sarcoma of the cecum, and the wound was closed. Although the tumor diminished somewhat in size after operation, the idea of malignancy was not relinquished.

At first I had no disposition to question the diagnosis, or the opinions of the surgeons to whom the case was submitted for examination. However, it was later noticed that the ice-bag, which was applied to relieve pain, caused a flattening of the growth, as though it were of a doughy nature. The mass filled the right iliac fossa and markedly encroached upon the region of the cecum. It was noticed, too, after a few days, that the size and tenderness of the tumor varied from time to time, in unison with the temperature fluctuations, and especially was this true when there had been much pain at the seat of the growth. These incidents, together with the past history, and the fact that the tumor had diminished in size after the first operation and was no larger now than at that time, caused me to exclude malignant disease as an element in the diagnosis, and to express a positive belief that the case was one of chronic fibrinous appendicitis.

An incision made along the line of the previous operation freely and promptly exposed the tumor. It involved the lower half of the cecum and extended

down nearly to Poupart's ligament, filling almost the entire iliac fossa. The tumor was hard and immovable. It was puzzling at first to fix upon a plan of exploration of the growth, as one did not care to incise it, fearing to cut the cecum. The fibrous band of the colon, commonly leading to the origin of the appendix, disappeared in the indurated mass, which could not be separated from the cecum without tearing away the serous covering, and thus laying a foundation for sloughing of the wall of that viscus.

After a little hesitation the sharp end of an ordinary periosteotome was introduced into the growth, in the line of the fibrous band before noted, and the growth pried open, thus dividing it into two parts of about equal size united below by the deeper tissues. At the line of separation the base of the appendix was seen extending indefinitely downward and inward into the mass. By the careful use of scissors and the patient application of the grooved director a complete appendix, about four inches in length and very much thinned at the lower end, was withdrawn from the indurated mass. No other evidences of inflammatory action than thickening of the appendix and moderate circumscribed congestion of the contiguous peritoneum were found outside of the appendix, save the mass already mentioned. The appendix was removed, the main portion of the wound closed, and gauze drainage established. The patient made an uneventful and complete recovery, and when last heard from was entirely well. The appendix was microscopically examined by Dr. Dunham and pronounced to be chronically inflamed throughout its entire structure, with muco-pus at the end, confined by the thinned walls of the appendix and a stricture of the lumen above.

The fifth case of this number came under my notice in Bellevue Hospital during the spring of 1897. A sturdy young man of good history was referred to my care, suffering from chronic appendicitis attended with fibroplastic induration. The tumor was well marked, somewhat tender, and the temperature fluctuated in accord with the occasional pains in the growth. Believing the case to be one of fibroplastic appendicitis, and not attended with immediate danger, it was decided to study its peculiarities for a few days before operation, with the entire and glad consent of the patient. For three days the temperature fluctuated from 100° to 102° F., *per rectum*, when there was a sudden chill, followed by sweating and a high temperature. On the following day the symptoms resumed the moderate trend which characterized the period before the chill. The next day a repetition of the same phenomena ensued. It was then ascertained that the patient had been at a comparatively recent date attacked by chills and fever. Quinin in suitable doses promptly reduced the temperature to 100° F., and the tumor began to rapidly disappear.

All of the previous symptoms nearly but not entirely disappeared. However, the patient desired that the appendix be removed, in which sentiment I fully concurred, and he was, accordingly, at once operated upon. No induration was found, and the appendix was intact, but contained an enterolith the size of a bean, lodged near the middle and bathed in mucopurulent fluid, a fact which I suspected because of the lingering tenderness and the trifling increase in temperature which had continued to characterize the case. The patient made a prompt and uneventful recovery.

It seems to me that the outcome of these cases suggests the following: (1) That an enormous deposit of lymph may be the only product of some forms of appendicitis. (2) That even though repeated attacks occur, suppuration is not a common complication of this condition. (3) That free incision of the mass attended by light packing with gauze, is followed by rapid absorption of the induration, and often by cure. (4) That suppuration may occur; therefore, the appendix should be at once removed, if practicable; if not, as soon thereafter as possible. (5) That chronic inflammation of the appendix, with fluctuation of a mild degree, provokes a response of apparently similar nature in the surrounding fibrinous mass. (6) That fibrinous induration due to chronic appendicitis, may be mistaken for sarcoma of the cecum.[1] (7) That the influence of malaria may stimulate the fibrinous variety of chronic appendicitis, and that possibly the symptoms may be dispelled by the use of quinin.

The remaining cases to which I shall refer are miscellaneous, and each in itself is pregnant with meaning.

A little more than a year ago a young man suffering from all of the marked symptoms of appendicitis was seen in consultation. It was noted that he had already gone through not less than two similar attacks; one some six years before, from which he was relieved by the opening of a large abscess. The second attack occurred some four years later, at which time he was taken to a private hospital, and his appendix was said to have been removed by the surgeon in charge.

In view of the history, and also of the fact that

[1] The last fact is still further strongly emphasized by the knowledge of another case which came to my attention at a medical meeting not long since, in which a surgeon, competent, eminent, and candid, acknowledged that he had recently removed the cecum for supposed sarcoma, only to find on careful examination of the specimen that it was a case of fibrinous induration caused by a chronic appendicitis. It is proper to say, I think, in this connection, that this patient also made a prompt recovery.

the patient was then improving, it was deemed inexpedient to operate. Therefore, the patient was admonished that should another attack occur, an explorative operation should be performed. He recovered from this attack, but soon experienced a second one, although not so severe as the first. He came under my charge during the abatement of the recurring attack, at which time there was no difficulty in finding and removing a complete appendix about three inches in length.

About six months ago I was requested to see in consultation a case of appendicitis in a young man of sturdy frame and active occupation. The illness began two days previously and was characterized by the usual though rather mild symptoms. At the time of my first visit there was tenderness, without tumor or tension; pain on deep inspiration; axillary temperature, 99° F.; pulse, 90. However, the symptoms had ameliorated since the day before. The patient objected to operation and was assured that there was no urgent necessity for interference. At the last moment it was suggested that the temperature be taken by the bowel, and 101.5° F. was registered. Careful observation of the condition was advised, and it was also recommended that in case the symptoms continued, the patient should be at once operated upon.

On the following morning the symptoms had increased in severity, and at nine o'clock the patient was admitted to St. Vincent's Hospital. The pulse was 99; temperature, 99° F.; tenderness and tension slight, and an entire absence of appreciable tumor. However, the patient was anxious, and vehemently urged an operation. Slight capillary paresis was noted, and an indefinite sense of nausea was present. For reasons unnecessary to mention, operation could not be performed during the next four hours. Nevertheless, it was done as promptly as possible, and at the time the pulse had arisen to 120 and the temperature to 104° F.

A dusky surface of the body at this time was plainly evident, and the patient's anxiety had markedly increased. Operation revealed the presence of a gangrenous appendix 4½ inches long, extending upward at the outer aspect of the ascending colon nearly to the hepatic flexure. The appendix was removed with some difficulty on account of its great length and the existence of firm adhesions at its upper end. On removal, the middle half was found to be completely gangrenous, but in no place had perforation occurred. Several small fecal concretions bathed in mucopurulent fluid were freely movable in its lumen. A grayish, offensive, and watery fluid was present around the site of the organ; little evidence of limiting adhesions was found. The wound was cleansed, dressed lightly with gauze, and the patient put to bed. In spite of all effort he died within twenty-four hours from the effects of the profound sepsis established prior to the operation.

This case illustrates several interesting and somewhat unusual features: (1) The marked length and unusual situation of the appendix is especially worthy of comment. In this case the appendix passed upward over the cecum to a position at the outer side of this viscus. The appendix is placed along the outer side of the colon and extends upward in about one in eighty instances in the male, and somewhat more frequently in the female. In about half the autopsies in males the appendix is found to be from four to six inches in length. (2) The unusual extent of the gangrene of the appendix at the time of operation indicated with absolute certainty the presence of gangrene at the time of the first visit. At all events, the history of the case at that time—less than twenty-four hours before—did not suggest the acuteness of the impending danger.

In appendicitis a comparatively rapid pulse with a low temperature is an ominous manifestation. The character of the pulse is of greater significance in these cases at the outset than is that of the temperature. The presence of an accelerated pulse with a rationally increased temperature at the outset need not be regarded as unfavorable. However, symptoms, like false friends, no matter how closely watched and discreetly treated, too often cause unexpected discomfiture.

The second of the miscellaneous cases is one which illustrates the outcome of successful surgical action on apparently mistaken hypotheses in a hysteric patient.

A female, about thirty-five years of age, with a distinctly hysteric tendency, was referred to me for diagnosis and treatment. The recital of her past history revealed the fact that she had suffered from persistent and annoying pain in the pelvic, right inguinal, and lumbar regions for a long time, for the relief of which the left ovary had been removed and right nephrorrhaphy practised some time before. Inasmuch as there remained only the appendix, uterus, and the right ovary, my attention was directed to their condition.

No evidence of ovarian, uterine, or broad-ligament disease could be found, a fact which was verified by the late Professor William T. Lusk. However, careful palpation disclosed the seat of the appendix, its extent, apparently increased size, and the presence, on moderate pressure, of the pain which had characterized her affliction. In fact, she exclaimed: "That is the same kind of pain I have had all the time."

It is hardly necessary to add that the appendix was removed. The patient made a prompt and satisfactory recovery so far as the surgical end of the affair was concerned, but the pain continued the same as before. Dr. Dunham examined the appendix, and reported the presence of a mild chronic inflammation of the walls and beginning gangrene of the lining membrane near the middle and at the seat of a small enterolith. Certainly, the justification of the removal is witnessed by the lesions found, irrespective of the operative outcome of the case.

At least one striking conclusion may be drawn from this case: the possibility of the presence of a gangrenous process in a chronically inflamed appendix, with no suggestive manifestations of its presence except the apparently increased size of the organ in question, and a pain on pressure which was not relieved by the removal of the appendix. Had the pain been absent, I doubt if the increased size of the appendix would have attracted attention. Since the removal of the organ the patient has submitted to removal of the right ovary, and is still anxious for further effort to relieve the pain which yet torments her.

Early last spring the late Professor Lusk requested me to see with him a lady who was suffering from a second attack of appendicitis. As the symptoms had much improved, delay, with the view of removal of the appendix in the interval, was agreed upon. About four weeks afterward he hastily summoned me again on account of another attack. The temperature was 103° F.; pulse, 110; local tenderness without tension or tympany was present. As it was then late it was thought better to await the developments of the early morning hours than to operate at that time. The violence of the symptoms increased, however, so that by the time the operation was performed (the following day) the temperature was 104.5° F., and the pulse 130. Increased pain, beginning tension and tympany were then present. The appendix was easily found, but removed with some difficulty, as from an old adhesion its extremity was adherent to the brim of the pelvis. At the middle of the organ there was found an enterolith the size of a kernel of corn, bathed in a thin mucopurulent, sanguinolent fluid. The temperature and pulse were nearly normal on the following day, and the patient made an uneventful recovery.

This case seems to me to illustrate the prompt and high degree of febrile action which may sometimes result from infection in appendicitis in the absence of even approaching perforation.

During the summer of 1896 a young, robust, though nervous young woman, came to my notice, complaining of moderate pain and limited tenderness on deep pressure at the seat of the appendix. The pulse was normal, but the temperature was slightly and continuously elevated. She had suffered thus for some time, and was regarded by her physician as having a mild form of chronic appendicitis. After observing her a few days it was advised that the appendix be removed, which counsel she gracefully declined, and soon, when somewhat improved, passed from my observation.

The following year I was again called to her bedside, and found her presenting in every respect the symptoms of the year before. During the interval she had experienced two or three light attacks. On this occasion she was anxious for a prompt operation. At this time the point of tenderness was well marked, and the presence of a small, tender tumor, the size of the first phalanx of the index-finger, could be easily determined on deep pressure. Operation was promptly performed, and the most careful scrutiny failed to disclose the evidence of the least inflammation, or even the presence of an appendix. She made a prompt recovery, and has not suffered in a similar manner since that time.

This case is of special anatomic as well as pathologic importance, for the following reasons: (1) the absence of the appendix, which, according to Ferguson, was found absent about once in 200 careful dissections. In 131 autopsies observed by Dr. Herman Biggs, at my request, some years ago, the shortest appendix was a quarter of an inch in length and in no instance was it absent. (2) A small tumor was found in the posterior wall of the cecum, in the line of the common origin of the appendix. This growth was the deep-seated tender point which was mistaken for a diseased appendix.

In conclusion, it seems to me that these cases, briefly depicted, illustrate respectively and in no uncertain manner, the fruition of discreet anticipation and the frost of unexpected fallacy.

SENILE EPILEPSY, WITH REPORT OF FOUR CASES.[1]

By CHARLES LEWIS ALLEN, M.D.,
OF WASHINGTON, D. C.;
LECTURER ON NERVOUS DISEASES IN THE GEORGETOWN UNIVERSITY.

WHILE epilepsy may begin at any age, in the great majority of instances the first attack occurs during early life. Gowers in an analysis of 1450 cases of epilepsy found that in seventy-five per cent. of them the disease began before the age of twenty. Between the age of twenty and thirty the percentage was 15.7, while from this time on it rapidly diminished until after the age of sixty years it was but one-third of

[1] Read at a meeting of the Medical Society of the District of Columbia, October 8, 1897.

one per cent. Other authors assert that in old age—after the sixtieth year—there is again a somewhat increased liability to the disease. It is certain that while not common there are cases in which attacks more or less typically epileptic come on in people of fifty-five years or over, who have never had such seizures before and in whom there is no evidence of gross brain lesion, of any source of reflex irritation, or of any intoxication capable of causing the attacks in question. By some authors all cases of epilepsy beginning after the thirtieth year are classed as "late epilepsy." When the disease appears first during old age it seems to differ somewhat from that which makes its advent during the prime of life. Since it is to the discussion of the epilepsy of old age that this paper is devoted, only cases in which the first paroxysm occurred after the fifty-fifth year, and in which the causal agents mentioned above are not present, will be considered.

Senile epilepsy was not unknown to the older writers, though its literature belongs in the main to recent years. Cases were described by Heberden, Trousseau, Maisonneuve, Herpin, Devay, Portal, and others, but the earliest monograph on the subject is the thesis of Jabot, published in 1890. He collected and analyzed fourteen cases from different sources and adds two observations of his own. Since then there have been a number of contributions to the subject, and senile epilepsy seems now fairly well established as a special variety of the disease. In the etiology of this form of the affection neurotic heredity may play a rôle, but it is a much less important factor than in early life. Indeed, it seems unlikely that a person having any strong hereditary predisposition would go throngh the period of greatest stress without developing the disease and should then be attacked by it in old age. It is to be remarked, however, that while ordinarily epilepsy is manifested about the time of puberty, when the nervous system is developing very rapidly and its cells are consequently in a state of unstable equilibrium, old age is a period in which degenerative changes are taking place and instability of nerve-cells is again a feature of body activity.

Syphilis and the abuse of alcohol may exert a causative influence in old age as at any other period of life, but the cases in which the attacks are the direct result of either of these agents are hardly to be considered as true epilepsy at any period of life. The same remarks apply to trauma, gross brain disease, and intoxications. Observations so far do not enable us to assign to senile epilepsy a course and symptoms differing in any marked degree from the epilepsy of earlier life. The seizure may come on suddenly or there may be prodromal symptoms such as dulness, buzzing in the ears, dim vision, or even local spasms. There may or may not be an aura. When the latter symptom has been noted it has generally been some sensation arising from the epigastric or precordial region. The attack may be one of *grand mal*, of *petit mal*, or an "absence" of any one of the changed mental states which constitute the epileptic equivalent. As to which form is most frequent, the experience of different observers is somewhat at variance. A study of the reported cases, however, and my own experience as far as it goes, leads me to think that while a convulsion followed by coma is perhaps the most usual form, the attack is apt to be atypical, the convulsion being but slight or entirely wanting—often only a short tonic spasm occurring—while the coma is quite profound, resembling closely the coma of apoplexy, and as this is the stage which the physician is most likely to observe, the latter disease is apt to be diagnosed, until the rapid recovery of the patient makes evident the true nature of the case. In fact the older physicians described the attacks as apoplectiform or pseudo-apoplexy.

The seizures do not generally occur with great frequency, seldom oftener than once or twice a month, perhaps only once or twice a year. They come on more frequently at night than during the day. There may or may not be tongue-biting. Involuntary discharge of urine is common. Vertigo, attacks of *petit mal*, and "absences," as well as slight localized spasms, are frequent, often antedating by some time the more severe attacks. After an attack of *grand mal* the patient may be in a dazed condition for several hours or days. Mental failure is common in the subjects of senile epilepsy, but it does not differ specially from that usual in old people, nor is the insanity which is sometimes present different from senile insanity in general.

The following cases have been observed by the writer during the past year:

Case I.—Mrs. M., aged seventy-four years; family history negative. She never had convulsions or any other nervous disease during her earlier life; had always led a quiet regular existence, and, until recently, had enjoyed good health. During some years she had digestive disturbances, and her nutrition had suffered somewhat. For several months previous to coming under my observation she had attacks, coming on about every two or three weeks, and presenting the following characteristics: She is noticed to be wandering about in a dazed condition. When spoken to she answers, but somewhat incoherently, talks about things and people having no connection with the time and place, and is entirely unable to locate herself. Upon being persuaded to lie down and to take a little stimulant she gradually recovers, and has absolutely no recollection of what

has occurred. These attacks are very apt to come on after some exertion such as mounting the stairs or straining at stool. She has also occasional attacks of giddiness but has never had convulsive movements of any sort. Examination showed a medium-sized and rather feeble woman. There was some tremor of the hands, rather coarse in character and not increased on movement; slight tremor of the tongue; no facial paresis; pupils equal and reacted to light and for accommodation. The movements of the hands and gait were normal; no ataxia; reflexes normal; no sensory disturbance; heart dulness of normal area. Heart action rather feeble; no bruit, but slight prolongation of the first sound. Arteries about the head somewhat hard and thickened; radial arteries normal. The urinary examination was negative.

She was given strychnin and cod-liver oil, and was directed to pay special attention to keeping her bowels open. During the spring she improved and in the summer was able to go for some time to the seashore. She is now (November) somewhat improved in nutrition, and since the beginning of the summer has not had more than three or four attacks. While there have been no convulsive phenomena, the attacks have all the characteristics of the epileptic equivalent, and should doubtless be considered as such.

CASE II.—Cornelius B., aged about seventy-five years, negro; knew nothing of his family history, and denied both syphilis and the abuse of alcohol. He had been married twice, and had had a number of children, all but one of whom died young. He enjoyed good health until seven or eight years ago when he had an attack of erysipelas, but on what part of the body he can not remember. Since then he has had fits on an average of about twice a month, though no accurate account of them has been kept. He feels a dulness and heaviness in the head for some time before the fit, but there is no aura. The attack is one of typical *grand mal*, consisting of tonic, then clonic spasms, followed by sleeping and dulness for some time, and he occasionally bites his tongue. The attacks occur most frequently at night, seldom by day. Examination showed him to be tall, well built, and very black. He presented marked arcus senilis. Examination of the lungs was negative; heart action rather weak; apex beat neither visible nor palpable; heart sounds clear; no bruit; area of cardiac dulness rather less than normal. Arteries, carotid and femoral, normal; brachial, radial, facial, and temporal, hard and thickened; pulse, 84 and regular. Liver dulness slightly less than normal, otherwise examination of abdominal organs was negative. Pupils small, did not react to light, but reacted for accommodation; no paresis or paralysis of any muscles; no sensory disturbances. Slight tremor of the hands; speech normal; reflexes normal; no trouble with bladder or rectum.

Since the patient was first seen he has continued to have hard fits about one or twice a month. The ward attendant, a fairly intelligent person, describes them as typical *grand mal*, and says they almost always occur at night, sometimes two or three in succession. At this time the patient looked older and more feeble, and the arteriosclerosis had progressed somewhat, but otherwise there was no change in the condition. He took bromids during the summer, but the attacks did not seem to have been to any extent controlled by the medication.

CASE III.—Mrs. G., aged seventy-four years; family history negative. The patient had led a stormy life, with much worry and hard work. She had possessed great intelligence, and had been very industrious, was always temperate, and had usually enjoyed good health until the beginning of her present trouble. There is no history of epilepsy or other nervous disease in earlier life. About thirteen years ago she was noticed to be failing mentally, but kept on for some time with her work as a music-teacher. At first she was melancholy, with occasional periods of excitement, but has never been suicidal or homicidal. For the last three years she has been demented and at times very restless and noisy. During August, 1896, immediately after coming from the closet, she suddenly fell on the floor in a tonic spasm. Her head was drawn to the left, limbs rigid, and her arms were extended over her head. There was no frothing at the mouth or tongue-biting. The convulsions lasted two or three minutes, and were followed by three hours of unconsciousness (deep sleep?), from which she was aroused by the entrance of a physician, spoke at once, and showed no paralysis. During May, 1897, she had another fit, coming on under similar circumstances, and in all respects like the first, except that it was not so severe.

The patient was a small, feeble old woman. There was no paralysis or alteration of gait or reflexes; no tremor. The lungs were normal; cardiac dulness of normal extent; heart sounds normal; no murmur. The pulse was seventy-five per minute and regular; tension increased. Arteries, especially those about the head, showed arteriosclerosis. Examination of the abdominal organs was negative, as was also that of the urine.

September 21st she had another fit similar in all respects to the previous attacks. Her daughter, whom I requested to particularly observe the character of her pulse should she have another attack, reported that it did not seem abnormal. October 10th, she fell into a state of unconsciousness which continued thirty-six hours, after which she recovered without any trace of paralysis. I was able to see her but a few times, and treatment was irregular and unsatisfactory.

CASE IV.—John D., exact age could not be ascertained, apparently between seventy and seventy-five years; lawyer. Admitted to hospital August 17, 1897. His family history was unknown. He was said to have had a convulsion seventeen years ago; no history of injury. Since then his mind has been weak, and he has not done any work. He has been restless and confused, has had delusions of persecution, and has threatened his friends. August 20th, he had a fit and fell to the floor, but soon recovered consciousness. The exact nature of the attack could not

be learned. September 7th he had an attack of *petit mal*.

Examination showed him to be a medium-sized, rather poorly nourished man. His pupils were equal, medium-sized, reacted to light and for accommodation. The tongue, when protruded, did not deviate from the middle line, and was without tremor. There was no paresis or sensory disturbance; speech good; reflexes normal; heart of normal size; first sound slightly prolonged, but there was no murmur. There was some thickening and stiffness of the arteries, especially of those about the head. Urinary examination negative. Mentally the patient was very weak. He was quite suspicious, and had delusions of persecution.

Cases of apoplectiform or epileptiform attacks occurring in old people, in which recovery is rapid and without paralysis, were known to the older writers, and were by them ascribed to cerebral congestion. Trousseau depicts such cases, and says that while he formerly regarded them as apoplectiform and congestive he later learned to look upon them as epileptic. In most of these cases it may be noted that there was disease of the heart or vessels. In the first half of this century Adams and Stokes published observations of cases in which coma and convulsions with extremely slow pulse had occurred in persons usually in advanced life, and in whom disease of the heart and arteries, generally fatty degeneration and atheroma, was found.

New observations have been recorded from time to time, and late writers have sought to establish the existence of a distinct disease, or better, perhaps, a symptom-complex, characterized by slow pulse and epileptiform or apoplectiform attacks, the anatomic basis of which is a sclerosis of the arteries of the medulla and pons with degeneration of the heart-muscle, and to which they give the name "cardio-bulbar-sclerosis," or after the authors referred to above, the "Stokes-Adams disease." The association of epilepsy with cardiac disease has been specially brought out in an admirable article by Lemoine. He describes three cases in which the epileptic attacks seemed directly due to valvular lesions, and divides the cases of heart epilepsy into two classes, due respectively to cerebral congestion and to cerebral anemia, the first having mainly mitral, the second aortic lesions. His cases, however, were all in young people. That acute anemia of the brain can produce epileptiform convulsions was long ago shown by the classic experiment of Kussmaul and Tenner. Now we well know that in arteriosclerosis the arteries are thickened and stiff and their lumina more or less encroached upon; hence, even a slight contraction of the muscular coat may have quite a powerful effect upon the blood-supply, especially in the brain. It seems likely that the vertigo, temporary numbness of extremities, and occasional local spasms, observed in the subjects of arteriosclerosis are due to local anemia produced in this way. Nerve-cells whose nutrition is disturbed become irritable, and the cells of the cortex may readily suffer when the arteries which supply this region are diseased. While the epileptic attack generally begins with a discharge of energy from the cells of the cortex, the researches of Nothnagel, Zichen, Bechterew, and others, seem to show that the tonic spasm at least may have its origin in the medulla and that from an irritation starting in this region the cortical cells may be secondarily affected. Again, by failure of the blood-supply to the medulla the vasomator center may be irritated and the cortical circulation may be secondarily influenced; so there may be either direct or secondary action upon the cortical cells.

Arterial sclerosis is specially a disease of old age. It has been present in greater or less degree in all the cases of senile epilepsy which have came to autopsy and has generally been accompanied by degeneration of the myocardium. This fact is especially insisted upon by Mahnert, who urges the necessity for separating this class of cases from heart epilepsy in general and grouping them together under the name of "senile arteriosclerotic epilepsy." While we may not always be able to determine the presence of any considerable degree of arteriosclerosis by surface examination, the location of the changes is very capricious, and we can by no means assume on that account that the arteries of the brain are healthy. An experience bearing directly upon the subject is furnished by Naunyn, who reports three cases of senile epilepsy, one with autopsy, and in all of which there was arteriosclerosis. By firm compression of the carotid arteries of these patients, the pulse could be brought down from 80 to 40 per minute, and an attack, varying from slight giddiness and muscular twitching to a full convulsion, could be produced. He then tried the same maneuver upon other people not the subjects of epilepsy, and found that while in young and healthy individuals no effect is produced, those having even a moderate degree of arteriosclerosis, experience unpleasant sensations in the head, as well as pallor, vertigo, and slight muscular twitchings. His experience coincides with that of Concato, Kussmaul, and Tenner. This result of carotid compression, known generally as "Griessinger's symptom," was formerly thought to indicate thrombosis of the basilar artery, but this has been found to be incorrect. In one of Naunyn's cases in which it was present, the basilar and vertebral arteries were healthy, while the carotids and sylvians were thickened and of diminished caliber.

Naunyn, however, gives warning of the danger of the procedure mentioned above, as one of his patients, after the pulse had been reduced from 96 to 40 per minute and a convulsion had been produced, stopped breathing, and artificial respiration was necessary to save life. In some of the cases of senile epilepsy which have come to autopsy foci of softening have been found in different portions of the brain, but it seems most likely that they have not been responsible for the production of the attacks, but have developed within the last few months of life, as they could hardly have existed for the number of years during which the fits were occurring without having given rise to some other symptom.

From the foregoing it seems likely that senile epilepsy, if not identical with, at least bears a close relation to the "Stokes-Adams disease," and has a similar pathology. It is evident also that it should hardly be termed an idiopathic epilepsy, but that it belongs rather to the ever-growing class of symptomatic epilepsies. When we consider, however, that of the great number of people having arteriosclerosis so few develop epilepsy, the arterial theory does not seem entirely sufficient to alone account for all cases, and we are constrained to survey the field for other factors. Of course, in different cases there may be different arteries affected, and the changes produced in the brain may vary in their location, but this is not an entirely satisfactory explanation. While neurotic constitution—hereditary or acquired —may play a rôle, it is not as important as in early life. A theory which is held by many with regard to epilepsy at any age is that the exciting cause of the attacks is the presence in the blood of some toxic substance produced in the body by disturbed metabolism, an auto-intoxication. Examples of such poisons are uric acid and kreatinin, and by the injection of the latter into the circulation convulsions have been produced in animals. All are familiar with the fact that in epileptics the fits are increased in number by constipation and excessive intestinal fermentation.

Haig insists that the excessive production or diminished excretion of uric acid is, in many instances at least, the exciting cause of the epileptic seizure. The subjects of arteriosclerosis are often of a uric-acid diathesis, and usually suffer from indigestion and fermentation, so, in them, auto-intoxication may readily occur. Hence, we must conclude that while disease of the heart and arteries and consequent disturbance of brain nutrition are probably the prime causes in the production of senile epilepsy, other influences, such as age, neurotic constitution, auto-intoxication, and reflex disturbances may play a rôle, and at times an important one.

The diagnosis is to be made by the exclusion of gross brain disease and intoxications, and after a careful examination this is not usually difficult. If the patient is seen for the first time during an attack there may be a question as to whether it is apoplectic or epileptic, and time alone may make the diagnosis clear. Epilepsy differs from ordinary syncope by its sudden onset, the convulsive movements, the complete loss of consciousness, and the absolute lack of recollection of the attack on the part of the patient. The minor attacks and "absences" may offer more difficulty, but a careful study of the case will generally make evident its nature even when severe attacks are not present.

That the prognosis is unfavorable is evident from the nature of the case, as arteriosclerosis is an incurable disease, and the fits constitute a direct menace to life. However, years may elapse before the fatal issue, and by suitable treatment a good deal may be done to favorably influence the course of the affection and to prolong life. As arteriosclerosis is practically always present a dietetic and hygienic régime suited to this disease should be insisted upon, and the appropriate medicinal treatment should be applied. The limits of this paper, however, do not permit of a detailed description of the management of arteriosclerosis and its results, and with it, probably all are familiar. The occurrence of the fits does not seem to be influenced by the use of bromids to anything like the same extent as in early life, In the cases of cardiac epilepsy reported by Lemoine, bromids were without effect, while by the use of the cardiac tonics, notably digitalis, the fits were very much diminished in number. Naunyn and others have had a similar experience in senile epilepsy. In arteriosclerosis, however, though digitalis is sometimes indicated when there is great failure of compensation, with edema, etc., it has the disadvantage of increasing the arterial tension, so for constant use strychnin and caffein will be found the better heart tonics. When the pulse tension is high, they may well be combined with nitroglycerin or with sodium nitrite. Mahnert suggests the combination of caffein and bromids in an effervescent drink. If causal agents other than arteriosclerosis are found they should be removed if possible. In any event attention should be paid to the digestive and excretive functions, and an effort should be made to combat anemia, if present, to regulate the circulation, and to improve bodily nutrition.

Gladstone to Undergo an Operation.—The laryngologists and rhinologists are again in evidence, and about to display their skill in an operation upon Mr. Gladstone to relieve the pain caused by necrosis of some of the bony structures of the nose.

PNEUMONIA IN PRIVATE PRACTICE.

BY M. HOWARD FUSSELL, M.D.,
OF PHILADELPHIA.

THE purpose of this paper is not the presentation of any new or startling discoveries in regard to the pathology and treatment of pneumonia, but rather the expression of the writer's opinion that it is worth while to record a series of fairly careful observations of this disease, as it occurs in private practice, in contrast to its somewhat different manifestations in hospitals.

In a series of cases of pneumonia Wells found the mortality to be 18.1 per cent.; thus it will be seen that the mortality in the 134 cases observed by me (16.4 per cent.) closely approximates that of Wells. Professor Osler has made the statement that pneumonia is one of the most fatal of the acute diseases, a statement amply borne out by my own as well as by the experience of others.

As will be seen by reference to the table, two cases occurred in patients over sixty years of age, neither resulting fatally; both were remarkable instances of recovery in spite of the presence of very extensive lesions, and as such are worthy of record:

CASE CXXXII.—A woman, aged seventy-two years, with marked mitral regurgitation—fully compensated. She was suddenly seized with a chill, pain in the right side, and high fever. On my first visit I detected signs of beginning consolidation, which finally involved the entire right lung. The disease ran an ordinary course, during which the heart never faltered, and ended by crisis on the seventh day. This occurred ten years ago and the woman is still alive, although it should be noted that she has never regained her previous good health.

CASE CXXXIII.—A woman, aged eighty-six years; as in the previous case there was present an advanced organic disease of the heart. She was suddenly seized with fever, which continued three or four days. Examination revealed consolidation of the base of the right lung. Before her death, which occurred eight weeks later, the lung condition entirely cleared, the fatal termination finally resulting from failing compensation.

It would appear from the table that in ordinary practice more than one-half the total number of cases occur previous to the tenth year of life, and the highest mortality is observed in infants less than one year old. Between the ages of five and twenty-one years there were no deaths in a total of thirty-two cases.

Causes of Death.—In 4 cases in which a fatal termination occurred, a history of chronic alcoholism was presented; 3 of these were in patients over forty-five years of age in whom cardiac and circulatory changes were marked. In 3 cases advanced cardiac disease was a concomitant. One patient collapsed and died within twenty-four hours after being told by a friend, on the fourth day of the disease, that she was "very" ill. Two cases occurred in pregnant women, both of whom aborted and died within a few hours. One case was in an exceedingly obese individual, such a one as is likely to die during any severe illness; death resulted on the fourth day. One patient was up and about the house when general collateral edema developed, and death resulted within a few hours. Six cases occurred in apparently healthy children, who succumbed to the disease without any contributory influence. Five fatal cases were in infants under one year of age.

Sex.—Sixty cases were in males, with 13 deaths—a mortality of 20.1 per cent.; 74 were in females, with 10 deaths—a mortality of 13.7 per cent.

Family and Personal History.—In all cases the family history was apparently negative; the same may be said of the personal history.

Contagion.—I observed 4 cases in one house in consultation, none of which are included in the table. The father was the first to be attacked, and in three other members of the family the disease subsequently developed at intervals of about one week. Four of my cases were each followed by a second in the same house. In none of these did there seem to be anything about the premises to suggest a common cause. However, 4 or 5 cases in a series of 133 is not a large number, granting the disease to be truly contagious, and the four mentioned may not have had any etiologic connection. In all the remaining cases there was the freest sort of communication between the patient and other members of the family. Often, a child was ill in a room where two or three others were compelled to sleep; none of these, however, developed pneumonia. There is then, in these cases, absolutely no proof of the contagiousness of pneumonia—at least by the ordinary means of transmission.

Complications.—Whooping-cough was apparently a contributing cause in 4 cases; measles in 2; alcoholism in 7, and, as said before, 4 of these terminated fatally. Five patients were the subjects of valvular disease of the heart, and 2 of these died.

Three women were pregnant, all of whom aborted, and 2 died.

There was one patient, the subject of diabetes, a woman aged forty years, and one, a child of seven years, of nephritis, both of whom recovered.

Duration.—The duration of the disease, from the first manifestation to the crisis, varied from one to fifteen days. In 16, the crisis occurred on the fourth day, on the fifth day in 11, on the sixth day in 8, on the eighth day in 9, and on the ninth day in 12 cases.

Seat of the Lesion.—The base of the right lung was affected in 27 cases, resulting in 5 deaths; the right apex in 27 cases, resulting in 3 deaths; the left base in 47, with 6 deaths; the left apex in 4, with no deaths; the entire right lung in 15, with 4 deaths; the entire left lung in 5, with no deaths, and both lungs were affected in 10 cases, with 6 deaths. Without reference to any other condition it may be said that the greater the amount of lung tissue involved, the greater the mortality will be.

Special Symptoms.—Signs of meningitis occurred in five cases, all in children under five years of age. In two of these the apex alone was affected, in two the base, and in one the entire lung. The symptoms consisted in severe delirium, opisthotonos, strabismus, and convulsions. Indeed, in some instances, the symptoms were so severe that a diagnosis of tuberculous meningitis was made, as an example of which Case XIV. may be cited: A child two years old, already ill with whooping-cough, suddenly developed a very high fever. On examination the apex of the right lung was found consolidated. On the third day the child had a convulsion, followed by marked strabismus, entire loss of sight, opisthotonos, and muscular twitchings, with the thumbs drawn into the palms. Considering the history of whooping-cough, with the very limited consolidation at the apex, it was decided that the child had meningitis of tuberculous origin. On the tenth day, however, crisis occurred, following which the signs of meningitis gradually disappeared. The child is now—five years after the attack—a strong, vigorous boy.

Signs of meningitis in pneumonia are well known, and are usually spoken of as occurring with lesions of the apex. In two of these cases, however, the base was affected. The lesson to be learned from the case just cited is that even in the face of most positive symptoms, meningeal signs accompanying pneumonia may usually be considered as symptomatic.

Irregular Temperature.—In several of my cases the temperature was so markedly irregular, actually intermittent, and the physical signs were so delayed that a diagnosis was not made for a period of three or four days. This was especially noted in the following case in which a fatal termination occurred: The boy, aged six years, was said to have fever. I saw him first during the morning, at which time the temperature was 98.8° F. The next morning I found him out of bed and running about the house. He presented a normal temperature and absolutely no symptoms, but a history of having had fever the previous evening. The next morning there was slight fever and some cough. From this time on the temperature became higher, marked physical signs developed at the right apex, consolidation rapidly spread throughout the entire lung, and the patient died on the tenth day.

Early Physical Signs.—The physical signs of an advanced consolidation are too well known to require mention. It has seemed to me, however, that the very first signs of approaching consolidation are dulness on percussion and weakening of the breath sounds over the affected area. These signs are far more constant than the famed crepitant râle, which when present, while a sign of beginning consolidation, is far too often absent to be of any great diagnostic value.

Signs of Crisis.—In a number of my cases I have observed the occurrence of a few fine râles of beginning resolution just before the crisis, from which I have been able to state correctly in a number of instances that the crisis would probably occur within a few hours.

Appearance of the Tongue.—In these days of exact diagnosis it may seem out of date to refer to the tongue of pneumonia, but the thickly coated, white tongue, with papillæ only less prominent than in the first stage of scarlet fever, with a red tip and edges, is often the first sign which marks the occurrence of pneumonia.

Fear of Falling.—This is another most characteristic symptom of pneumonia in children. During the first few hours or even days of illness, before the physical signs are evident, a child will have constantly high fever, and will lie still if undisturbed, but the moment it is lifted, it clutches at the nurse and manifests great fear of falling. This symptom has become to me almost pathognomonic in children.

Pain in the Abdomen.—Children constantly place their hands over the abdomen and say they have stomach-ache when questioned as to whether or not they have pain. I once made a post-mortem examination in a case in which the child had been un-

manageable, physical diagnosis impossible, and in which the only symptoms were irregular fever and abdominal pain, with much distention. A diagnosis of enteritis had been made. The autopsy showed a consolidated lung with empyema. I recently saw a case of complete consolidation in a child of six years in which the only symptoms were abdominal pain and a temperature of 100° to 102° F. This pain, of necessity, originates in the irritated intercostal nerves at the site of the inflamed pleura. Its cause is the same as that which gives rise to the expiratory moan.

Physical Sounds.—It is a notorious fact that the physical signs of pneumonia in children are anomalous. They may be almost indefinitely delayed or finally appear when the child is almost convalescent, and the same is occasionally true in the case of adults. In Case LXXVII., that of a girl, thirteen years old, there were no definite physical signs until the fourth day, when they suddenly appeared. In Case XCII., a man, twenty-six years old, the physical signs did not appear until the fourth day, and the symptoms and history were suggestive of typhoid fever. Only careful repeated examination established a diagnosis of pneumonia.

Complications.—Nephritis occurred in two cases, in both of which there was complete recovery, casts and albumin disappearing from the urine about a week after the crisis. In neither case did the kidney affection give rise to symptoms, and in neither was treatment directed to this condition. In one case, a child, aged six years, empyema followed a rather severe attack of pneumonia; recovery was complete after tapping and drainage. Delayed resolution characterized three cases, in none of which was tuberculosis a sequel.

Prognosis.—In an acute disease having a mortality of eighteen per cent. the prognosis must necessarily be guarded; but given an individual, in private practice, between the ages of two and thirty years, with a sound heart, and possessing tissues not degenerated by the excessive use of intoxicants, one can with a good deal of confidence foretell recovery. Two important characteristics of pneumonia must, however, be remembered: the local lesion and the systemic poisoning. In many cases there are extensive lesions, and yet, aside from the discomfort attending the involvement of such an important structure as the lung, there is little suffering. On the other hand, in many cases in which the local lesion is comparatively insignificant the systemic poisoning is so severe that death often and suddenly occurs.

Treatment.—In a disease in which, in fully one-half of all cases, treatment is apparently ineffectual, and in which recovery is frequent even when treatment is not attempted, the cases not being seen by a physician, one must speak of the value of remedial measures with great diffidence, especially as regards drugs. I believe that much good may be accomplished by proper treatment, and that it is criminal to permit a patient with pneumonia to be wholly without treatment, but I also believe that the administration of drugs or the use of local applications have absolutely no effect upon the course of this disease. In my opinion proper treatment consists of rest and care of the heart. Rest is certainly the most essential point in treatment. In Case CXXIV., the patient was doing well; there was no sign of collapse. I saw her at 10 A.M., at which time the temperature was normal and the pulse slow and steady. She arose from her bed, walked around the room, and within two hours was dead from failure of the circulation.

I have just seen a case in consultation, not included in my list, in which resolution was progressing nicely. The temperature was normal. The patient had violent post-febrile delirium. The action of her heart, which had previously been good, became rapid and irregular. A few hours' rest, obtained by means of morphin, caused the heart's action to become regular, and the patient is now well on the way to recovery.

Rest should be as absolute as possible. The patient should not be allowed to rise to have a movement of the bowels, but should use the bed-pan. If delirium is present, a hypodermic injection of morphin should be given. I once acted as nurse for a noted homeopathic physician who could not be restrained in bed; he was maniacal, attempting to climb out of the window, etc. His pulse was very rapid. A hypodermic injection of $\frac{1}{8}$-grain of morphin put him to sleep; his pulse fell to 100 and was for the time much improved in quality. A consultation of his homeopathic attendants resulted in detention in bed by physical force. The delirium continued, and the patient finally died.

The next most important part of treatment is care of the heart, in regard to which rest is, of course, the prophylactic measure. When, in spite of absolute rest, the heart begins to fail, strychnin, digitalis, and whisky must be used. Strychnin, given hypodermically, will frequently abort a threatened collapse and carry the heart over a critical period. It has been said that such treatment is not rational, because it is but a whip to the jaded horse. That it is a whip is true, but if the tired heart can be made to make an extra effort and pull the load over the last acclivity it may be all that is necessary to insure recovery. In all cases of impending heart-failure I give strychnin hypodermically in $\frac{1}{30}$-grain

doses every three hours. Its value is well illustrated in Case CXIV., in which a man, aged forty-seven years, with double pneumonia and moderate fever, progressed nicely until the sixth day. The heart's action then became rapid and the respirations reached the extraordinary rate of seventy per minute. This condition continued from 7 A.M. until midnight. For some unknown reason strychnin had not been used, though oxygen, digitalis, and whisky had been employed to the fullest extent. At 8 P.M. a hypodermic injection of $\frac{1}{20}$-grain of strychnin was given, and was followed by some relief. It was repeated at 10 P.M. and also at midnight. By 2 A.M. the respirations had fallen to 50, and from this time on convalescence was rapid. Digitalis and whisky, I believe, are valuable agents in pneumonia, but in an emergency their action is not to be compared with that of strychnin.

Venesection.—I have never employed venesection in pneumonia. In one case it seemed to be demanded, but was refused. With aconite and veratrum viride I have had no experience, having always been afraid to use them.

External Applications.—In all my first cases of pneumonia a jacket poultice was employed. It was troublesome, unclean, and uncomfortable, and, except under certain conditions, was soon discarded. Where there is much pain, and consequent embarrassment of breathing, the application of a poultice which envelops the whole chest affords such immediate and striking relief that its use seems justified.

When pain is severe, a small hot poultice over the affected area will give relief. Cotton jackets I still use, but I must confess, knowing that they accomplish little or nothing except perhaps to quiet the minds of the patient and friends.

Cold.—A cold bath when the temperature is high gives the greatest relief, and under its influence a delirious patient will frequently go quietly to sleep. In Case XXXVII., in which the patient died with a temperature of 107° F., I believe the fatal termination might have been prevented by the application of cold.

Local applications of ice to the affected side are theoretically correct. They certainly relieve pain, but my own experience with them has not been encouraging. I *still* employ them when there is a tendency to hyperpyrexia.

The pain, which is frequently the most annoying symptom, can best be relieved by the application of ice, a poultice, by means of cups, and, last, by the administration of opiates.

Imperial Measles.—According to the daily papers, the Empress of Russia is suffering from a slight attack of measles.

THE EARLY DIAGNOSIS OF MALIGNANT UTERINE DISEASE.[1]

By L. GRANT BALDWIN, M.D.,
OF NEW YORK;
GYNECOLOGIST TO ST. PETER'S HOSPITAL, BROOKLYN.

THE statement that malignant disease of the uterus is a frequent cause of death, will not, I am sure, be disputed, and likewise, I take it, it will not be denied that if seen sufficiently early, cancer affecting any part of the uterus is amenable to surgical treatment, and when such is applied according to the best modern methods, it offers, in many cases, brilliant chances of either saving or greatly prolonging life; *i.e.*, if a case is seen when the disease is confined to the uterine tissue itself, and before either the blood-vessels or lymphatics are involved, a complete hysterectomy will add to the days and comfort of the patient, if not effect a permanent cure. Unfortunately, however, the happy combination of circumstances which I have sketched does not usually obtain; quite the contrary, when the case first comes under observation the disease is discovered to have already progressed beyond those limits within which a hysterectomy may be performed, and in many cases not even a palliative scraping followed by cauterization offers any considerable chance of relief. Indeed, the infection is usually so far advanced that any interference will only serve to hasten its progress.

The hope that my efforts may be in a slight degree productive of a change which will bring these cases sooner under the care of the surgeon must be my excuse for asking attention to this subject.

Of the twenty-seven cases of cancer of the uterus observed by me during the past eighteen months in hospital and dispensary practice, twenty-four were beyond any operative treatment, and to only one patient could I offer hopes of permanent relief. The cases seen in private practice have made a decidedly better showing. In this respect I have no doubt that my experience is in line with that of my colleagues. There is a widespread tradition among both the members of the medical profession and the laity that at or near the menopause a woman is licensed to encounter all sorts of symptoms and conditions, which, occurring at any other period of life, would be considered abnormal and require the most rigid investigation as to causation, but when manifested at that time are regarded only as a part of the ills to which flesh is heir, and are thought by both family physician and patient as due to "change of life." Many may doubt the truth of this, but possibly it will strengthen the argument when I say that in all the cases given as having been seen during the past eigh-

[1] Read at a meeting of the Kings County Medical Association, January 11, 1898.

teen months such a belief was universally expressed, either quoted from the family doctor or stated on the patient's own authority. In many cases the physician consulted had not even suggested an examination after eliciting the gravest symptoms, and the patient had left with a prescription for ergot and a promise of recovery when the "change" was over.

The following is the history of a case which will serve as an example, and is, I promise you, no exaggeration colored for the occasion:

CASE I.—Mrs. J., aged forty-three years, a native of Ireland, married twenty-five years, and the mother of ten children, the youngest being seven years old. She had never had a miscarriage. She had been ailing eighteen months. She was well nourished, had not lost flesh, and looked the picture of health. Her only symptom up to three months before coming under observation had been gradually increasing menorrhagia and metrorrhagia; no dysmenorrhea, *no foul-smelling discharge*, and *no pain* between the menstrual periods. Up to this time she had not consulted a doctor, believing, as she said, that as soon as the change was over she would be all right. For the last three months she had suffered much from irritability of the bladder and painful defecation, and had seen two physicians who, she said, agreed with her opinion of the case. Examination revealed malignant disease of the uterus. The womb was absolutely fixed in the pelvis by extension of the disease to the broad ligaments, bladder, rectum, and vagina, and the condition was, of course, inoperable.

The symptoms of cancer of the uterus which I learned as a medical student, at least the ones which were prominently mentioned, were pain, loss of flesh, a cachexia, and a foul-smelling discharge, and to a great extent these are the symptoms especially noted in many of the text-books of a few years ago. It is true, minor symptoms are given, but stress was not laid upon them. I am convinced that I was not taught differently from many others from the fact that I constantly have these symptoms put forward in a consultation to prove, by their absence, that the case under consideration is not one of cancer; and especially is this true of pain and cachexia.

In my judgment, when a case presents any one of these signs or symptoms to any considerable extent it will matter but little whether or not a diagnosis is made, for the patient will have left behind the hope of successful treatment weeks if not not months before.

A natural inquiry is: Why are the effects of malignant disease of the uterus so different from those of the same disease in other organs; in the stomach for instance? My reply is that when the uterus is the organ attacked these grave symptoms are late in appearing. The uterus is not normally a highly sensitive organ. It is well known that the cervix may be cut or pricked to a considerable extent without causing very much pain, and in the development of a cancer of either the cervix or body of the uterus there is but little pain until such time as the new growth causes pressure on the great nerve trunks, involves the peritoneum, or effects by extension the bladder or rectum. The uterus having no connection with the chylopoietic viscera but slight inroads are made on the general health of the patient until adjacent organs or structures are infiltrated.

Some authorities attach especial importance to a foul-smelling vaginal discharge as diagnostic if not pathognomonic of cancer involving some part of the genital tract. That cancer of the uterus gives rise to a peculiar smell I do not for a minute believe. The odor comes from either sloughing tissue or decomposing discharge. Only recently I saw a sloughing fibroid which protruded from the cervix in which a diagnosis of cancer had been made from the odor. In many of my cases the general health was excellent, and yet the uterus was completely infiltrated with cancer. What, then, is there that should direct the attention of the physician to the uterus and that indicates a vaginal examination? The first step to an earlier diagnosis of this most terrible affection is education of the laity, with the end in view of destroying the idea that the menopause is an abnormal phenomenon, attendant upon which the sufferer is sure to nearly if not quite bleed to death every two to six weeks, for a period ranging from six months to as many years. I promise this is no exaggeration of what I have been told over and over again, and if any one doubts, to be convinced it will only be necessary for them to make some investigations on their own account. How this education is to be accomplished I cannot say; but for my own part I do not miss an opportunity of explaining the falsity of such conclusions.

The one sign of malignant disease of the uterus which should always be investigated, and especially so when it occurs at or near the menopause, *is hemorrhage*. We may say, I think, that in *all* cases in which the menstrual period becomes prolonged, the flow more profuse, or the interval shortened, the most rigid examination, no matter what the condition or age of the patient may be, is demanded. In all cases which I have observed bleeding has been the earliest symptom. This is probably more particularly so when the disease originates in the body of the uterus; as from the cavity of the organ comes the normal menstrual flow, it is natural to conclude that any new growth in this situation would cause a variation from the normal. It not infrequently happens that a woman will pass through the menopause without any untoward symptoms, and yet at a subsequent time be taken with a bloody discharge from

the vagina. This is, of course, especially suspicious.

A well-marked case of this kind was seen by me last May, with Dr. J. W. Parrish:

CASE II.—Mrs. F., aged sixty-three, native and resident of Long Island, had a normal cessation of menstruation at the age of forty-eight. For about three months prior to her visit to Dr. Parrish she had noticed a slight show of blood at frequent intervals, becoming constant, but never profuse, in fact only a few drops during the twenty-four hours. There was *no odor* to the vaginal discharge.

Bimanual examination revealed a small uterus, but yet too large for one not functionating for nearly twenty years. The cervix was somewhat eroded, and blood could be seen oozing from the external os.

A curetting brought away some small particles from the cavity of the fundus which were proven by the aid of the microscope to be carcinomatous. Vaginal hysterectomy was performed. I examined her during December, 1897, and there is as yet, eight months after operation, absolutely no evidence of any return of the disease. In this case the symptoms began the longest time after the menopause I had ever observed, and she came under observation with the least possible delay.

In some cases the bleeding is caused by coition at a period earlier than that at which any derangement of the menstrual flow is noticed. This is especially true when the disease has its origin in the cervix.

Another comparatively early symptom is an intermenstrual, watery, irritating discharge, but not necessarily foul smelling. This, when the disease begins in the cervix, may precede any change in the amount or frequency of the catamenial flow, but, very generally, it soon becomes stained with blood. Of course, I do not intend to infer that malignant disease of the uterus will be found in all cases to be the cause of hemorrhage from the vagina, but I do say that in all cases a cause of the bleeding may be found and that it should be sought for and if possible removed. If it is proved to be a result of some benign condition so much the better for the patient.

In nearly all cases coming under observation at a period of the disease sufficiently early for total extirpation of the uterus, to offer any reasonable hope of a cure, will require for diagnostic purposes a preliminary scraping, and a microscopic examination of the material removed.

In conclusion let me say that the cessation of menstruation is a natural transition from the active to the quiescent state of the sexual life of the human female; as natural, indeed, as its inception at puberty. True it is that this is a critical time in a woman's life, but this fact only makes it more imperative that we, as physicians, should investigate symptoms occurring at this period, and not permit either ourselves or our patients to attribute them to that much abused condition—"change of life."

CLINICAL MEMORANDA.

TWO CASES OF MALARIAL FEVER.

BY ALDRED S. WARTHIN, M.D.,
OF ANN ARBOR, MICH.;
INSTRUCTOR IN PATHOLOGY IN THE UNIVERSITY OF MICHIGAN.

TWO very interesting cases of malaria came under my observation during the summer of last year which emphasize certain important clinical points in regard to this disease.

As house-physician in the Manitou Park Hotel, Torrington, Colorado, during my summer vacation, I was asked to see one of the guests, a young lady from St. Louis, who was having a very severe chill. The paroxysm being typically malarial, I at once made a microscopic examination of her blood and succeeded in finding the large pigmented forms of the malarial organism. Quinin was withheld, and on the second day afterward, two hours before the second chill, the organisms were found in large numbers. The diagnosis of tertian malarial fever being established, the patient was given the regular quinin treatment, and as a matter of course promptly recovered.

Three months before in St. Louis the patient had had an attack of what was diagnosed as typhoid fever by a homeopathic physician who gave her an irregular quinin treatment. Recovering within two weeks, she came to Colorado, and had been well up to the time of the second attack. The patient's description of her first illness corresponded precisely with that of malaria, and there is no doubt in my mind that that was the disease.

The second patient, a male, from the same locality, left the Mississippi Valley eight months before, after a severe attack of malaria which was diagnosed and treated as such and apparently entirely cured.

A typical malarial paroxysm occurring without premonition, the patient's blood was examined and the organisms found. He was left without quinin until the third chill—the disease being of the tertian form—and the organisms were found in abundance two hours before the expected paroxysms. This case was also promptly cured by the usual quinin treatment.

Manitou Park is a mountain valley about 7750 feet in altitude, covered with pine forest, of sandy soil, its only water being a clear trout stream. The climatic and telluric conditions are as opposed to those favoring malaria as one could well imagine. That the malarial organism is indigenous here can hardly be believed, and the cases must be looked upon as importations. The fact of previous attacks in malarial regions bears this out.

The cases, then, are interesting because of the long time elapsing after the first infection, the long residence in a non-malarious region without symptoms, and the sudden outbreak of the disease under such favorable climatic conditions.

Cases developing within the second season after return

from Africa have been noticed at Berlin; and Osler and Mannaberg also report cases of an incubation period extending from one season to the next. The development of the disease within short limits of time after leaving malarious regions are by no means rare.

It is evident that malarial organisms may remain quiescent in the body for a long period of time, and suddenly become active under the most favorable conditions of climate and altitude. These conditions apparently have no effect upon the development of the organism if the body has been previously infected.

One of these patients was thought to have "mountain-fever." While there is no doubt in my mind that the majority of cases classed under this head are typhoid, yet it is probable that some, if not a large number, may be imported cases of malaria. It is an exceedingly common thing for residents of the Mississippi Valley to come to Colorado to recuperate after an attack of malaria. Many of them have attacks of so-called "mountain-fever," and it s probable that some of these may be attacks of malaria as in my cases. I simply suggest this, hoping that future blood-examinations may settle the question in those cases of fever occurring in visitors to the State of Colorado.

Dr. Sewall of Denver (*Colorado Med. Jour.*, September, 1896) reports a case of remittent fever in which the malarial plasmodium was found by Dr. Crouch in a patient originally from Louisiana, but who had not been out of Colorado for five years. I did not have access to Dr. Sewall's paper until after writing the above and after my return to Ann Arbor. I find that he has preceded me in the suggestion that some cases of "mountain-fever" may be malaria, and in calling attention to the importance of a blood examination in this disease; my cases, therefore, lend support to his suggestion.

NOTES ON CASES OF SYPHILIS.

BY JAMES C. JOHNSTON, M.D.,
OF NEW YORK;
DERMATOLOGIST TO THE NEW YORK LYING-IN HOSPITAL; PHYSICIAN TO THE CLASS OF SKIN AND GENITO-URINARY DISEASES IN THE OUT-DOOR DEPARTMENT OF THE PRESBYTERIAN HOSPITAL.

Syphilis Vegetans.—This condition is generally believed to be a result of mixed infection. My case occurred in a German women, fifty-nine years of age, living with unhygienic surroundings, and her person being undescribably filthy. No history was obtainable, but she showed unmistakable syphilitic ulcers of the upper third of both legs. On the dorsum of the right foot, extending from the joint flexure to the end of the metatarsal bones, was a patch composed of smaller lesions partially fused at their bases. The original efflorescence had been an ulcer which, spreading peripherally, had taken on vegetative overgrowth, directly analogous to the process which converts pemphigus vulgaris into pemphigus vegetans. The patch had been in existence some months so that time had been ample for the cauliflower appearance of the vegetations to be obscured by a thin covering of newly formed epidermis. The excrescences, though fused at their bases as mentioned, were separate and distinct above, each being rounded to a slight eminence. The color, after thorough cleansing with green soap, was pink; there was no crusting and no ulceration. The borders of the patch gradually faded into the surrounding skin.

Antisyphilitic medication in these cases usually has no more effect than upon the "parasyphilides," affections which are not luetic in themselves, but flourish upon the syphilitic soil, of which the pigmentary syphilide and paresis (in most cases) will serve as examples. Surgical measures must, as a rule, be taken for the removal of the vegetations, such as curetting, excision, or the use of the cautery. Pressure applied by elastic bandages or plaster dressings has been used, but in this instance a good result was obtained by covering the patch with mercury plaster and by pushing the administration of iodid of potassium until the patient was taking 60 grains three times daily. The plaster should be removed, and it and the surface cleansed twice daily. A new piece is necessary only every second or third day.

Syphilitic Paronychia and Onychia.—Syphilitic paronychia occurs in three forms: (1) dry, (2) inflammatory, and (3) ulcerative. The clinical phenomena in the first two classes usually appear early in the course of the disease. The ulcerative case to be described began close to the end of the second year.

The man, a butcher by trade, had received little or no treatment since the disappearance of his early eruption. Following a slight injury there appeared at the border of the nail on the right middle finger, a hard, indolent papule, which soon ulcerated and spread along the groove and beneath the nail, raising it from its bed. When first seen, the crateriform ulceration was a quarter of an inch in diameter. The discharge from the sore was thin and ill-smelling. The ulcer was shallow and uneven, covered by unhealthy, apparently gangrenous granulations. The nail, loosened to the extent of one-half its width, had lost its luster, was deeply ridged longitudinally, and of a yellowish color. Nosophen was dusted over the surface, and when in combination with potassium iodid administered internally it had set up reparative action, it was replaced by mercury plaster. The latter restrains exuberant granulation in addition to its stimulative action. Recovery followed, complete, except for a slight deformity of the nail on the affected side.

This paronychia must be carefully distinguished from the simple, non-syphilitic and the diabetic varieties. Differentiation is often difficult. The therapeutic test is worthless. A curious fact, worthy of note in connection with these paronychial gummata, is that they are prone to occur at the site of an extragenital chancre of the finger, as is too often seen in medical men. The gumma differs very little from the primary lesion.

Syphilitic onychia also has three recognized forms: (1) the *onyxis craquelé* of Fournier, in which the nail is cracked and broken; (2) the form in which it is partially or entirely shed; (3) hypertrophic onychia. My cases belong to the second variety, and the one described will serve as a type.

The patient, a young woman, first visited the Presbyterian Hospital during June last whith a chancre of the lip, the result of kissing a syphilitic subject. It was fol-

lowed by a rather severe form of the disease, the mouth lesions being particularly annoying. She was progressing fairly well with treatment by means of inunction, when, during October, my attention was accidentally drawn to the nails. Those of the thumb, middle, and little finger of the left hand, two of the right hand, and the nail of one great toe were affected. Involvement of the fingers is rather more common than the toes in these cases; of the latter, the great toe is most often attacked. The nails were marked with longitudinal furrows, were lusterless, yellowish, with a multiplicity of *flores unguium*. The lunulæ had disappeared, and in every one separation had taken place at the posterior border. The line of adhesion to the bed could be seen by pressing down the free end. After complete separation from the matrix the old nails continued to move forward leaving the bed bare between them and the new appendages, which were soon formed.

The new nails are ridged at first, but soon attain their proper shape. The process is slow but entirely painless. Inflammation is not present. The prognosis is good under treatment. Local measures are unnecessary if constitutional treatment is actively pursued. Between the time of the fading of the eruption and disappearance of the chancre, the patient was taking quarter-grain pills of mercury protoiodid, four times daily. On observing the onychia, they were discontinued and nightly inunctions of a dram of mercurial ointment were employed instead. The patient is progressing favorably.

Paresis Illustrating the Motor Type of the Disease.—In view of the claim, according to Fournier ("Les Affections Parasyphilitiques," p. 137, *et seq.*), that syphilis is an etiologic factor in sixty to eighty per cent. of all cases of paresis, the introduction of the subject here is as proper as any of those previously considered. The case in question is of peculiar interest because of the change observed by neurologists (Collins, *Post-Graduate*, January, 1898) in the character of the symptoms during the last few years. It points a warning, also, to syphilologists, to be careful in giving an opinion as to the ultimate outcome of syphilis even with proper treatment.

The patient is a man, aged thirty-five years. He gives a clear history of syphilis acquired ten years ago, for which he was under treatment (in good hands) for a year or more. The present illness began, according to his account, six months previous to my first examination, but it is likely that the insidious onset remained unnoticed for some little time. The first symptom noticed was difficulty in movement, interfering with his occupation; that which brought him to the clinic was incontinence of urine. He presented none of the mental phenomena formerly so common, no exaggeration of ideas as to his own importance, material circumstances, etc. Except for a certain slowness in comprehending and answering questions, his mentality appeared little changed. The motor symptoms were, on the contrary, thoroughly developed. His gait was paraplegic, the toes being dragged upon the ground, and it was almost impossible for him to accomplish the buttoning of his coat. His grip was feeble, slightly better in the right than in the left hand. The Romberg symptom was present, the knee-jerks exaggerated, and ankle-clonus marked. It was not practicable to have the eyes thoroughly examined, but the pupils were unequal, the left being larger, and they failed to react to light. The characteristic, slow, scanning speech of general paralysis and the difficulty in phonation were marked. Elision of consonants and lack of control of lip- and tongue-movements formed a close resemblance to the vocal effort of the inebriate. It was, in fact, difficult to determine whether the slowness in answering questions was due to difficulty in phonation or to impaired understanding. The patient stated that his attention had not been previously drawn to the changes in his speech. His digestion seemed good, and with incontinence of urine there was no lack of control of the sphincter ani. Iodid of potassium and tincture of belladonna were given in the hope of ameliorating, if only for a time, the distressing affection.

A CASE OF SPLENIC ANEMIA, OR SPLENIC PSEUDO-LEUKEMIA.

By HERBERT MAXON KING, M.D.,
OF GRAND RAPIDS, MICH.;
PHYSICIAN TO BUTTERWORTH HOSPITAL.

JANUARY 5, 1897, I was consulted by a young woman for the relief of pain in the throat which attended the act of swallowing. The patient was twenty-one years of age, unmarried, and was born in Sweden; she had been employed as a servant in the household of a small family for upward of six months, and occupied this position at the time of the examination. Some ten days before consulting me she had "taken cold," and had experienced pain upon swallowing food (both solid and liquid) ever since. She regarded this sore throat as a very trifling affair, and would not have consulted a physician except that her employers had insisted that she should do so. Her father was living and in good health. Her mother died at thirty-six years of age from consumption, and the maternal grandmother also died of consumption, while one sister had what in all probability (judging from description) was tuberculosis of the knee-joint. Upon examination the skin and mucosa were found markedly anemic. The pulse was 80, full and regular, and the temperature normal. Examination of both thoracic and abdominal viscera was negative, with the exception of the spleen, which was sufficiently enlarged to be easily palpable and was slightly sensitive to pressure. The nares and nasopharynx were normal, except for the anemic mucosa. The posterior wall of the middle pharynx was hyperesthetic and covered with a thin layer of viscid mucus. With the exception of the pale color of the mucous membrane, the larynx was also normal. At this time I considered the case one of mild pharyngitis complicating a depraved general condition. The patient was given iron, manganese, and quinin. Simple local treatment sufficed to relieve the pharyngeal symptoms.

I did not again see the patient until February 25th, when she came to my office (again at the request of her employers) complaining of pain in the left side, a general indisposition to work, loss of appetite, fatigue upon the slightest exertion, and a return of the pain on swallowing.

The appearance of the patient at this time was startling to say the least. Seven weeks before she had been anemic, but not more so than would be accounted for by many unimportant departures from the normal standard. Now, however, the skin was very sallow, and the lips, conjunctivæ, tongue, and nails were colorless. In fact, the whole appearance was at once indicative of the existence a very grave condition. Upon this occasion I made a much more exhaustive inquiry into the personal history of the patient, from whom I obtained the following, as having some possible etiologic bearing upon the case: When a very young child the glands at the angle of the jaw on the right side became enlarged and suppurated. The patient remembered little about them except that they were called "scrofulous sores," the cicatrices of which were quite conspicuous. At the age of ten years she had scarlatina, after which recovery was perfect. At seventeen years menstruation began, and the epochs have shown no irregularity since then except upon one occasion three years ago, when two or three months passed without menstruation. For the first year menstruation continued five to six days, when it fell to three or four days, and never continued more than three days after the patient was nineteen years old. Recently the periods had been still shorter, until at the last menstruation, February 15th, it continued but one day. She had had an inconsiderable leucorrhea during the past two years.

During March, 1896, the patient was sent to Butterworth Hospital, where she was treated for remittant malarial fever in Dr. Hugo Lupinski's service. Upon examination I found a slight edema of the face and lower extremities. Palpation of the abdominal viscera at once disclosed the presence of an enormously enlarged spleen. It had increased to double the size noted at the first examination, the splenic dulness beginning in the axillary line at the seventh rib and extending downward to the crest of the ilium and forward to the median line. On this account respiration was somewhat embarrassed, while the obstruction to the return circulation explained the edema. An anemic murmur over the somewhat displaced heart could be easily heard. The patient had lost in weight but was not emaciated. There was present, however, the severe anemia and a "lemon-yellow" color of the skin. The urine was practically normal, a specimen of which, obtained about this time, gave a specific gravity of 1017, was acid in reaction, and albumin, sugar peptones, and bile were absent; urea 6 grains to the ounce. A centrifuge precipitate gave only normal epithelial cells from the vagina, bladder, and possibly a few from the pelvis of the kidney; no casts or crystals, and a very small number of pus-cells, doubtless from the vagina. Repeated examination of the urine gave about the same result. Upon the several occasions of recording the temperature it was found to be 100° F. The pulse was small, wiry, and remained in the neighborhood of 100 per minute.

A careful examination of the patient's blood revealed the following condition:

Erythrocytes, 1,875,000 per cubic millimeter; leucocytes, 4685 per cubic millimeter; proportion, 1 to 400; hemoglobin, 35 per cent.; color index, .95 (approximately).

Qualitatively, the leucocytes were not far from normal, although eosinophiles were fewer than I have commonly found them. The red cells showed a somewhat greater departure from the normal, there being some poikilocytosis (not marked), while microcytes were more numerous. Aside from the presence of an occasional normoblast there were no nucleated red-cells. The results of the blood examination safely excluded the various forms of leukemia. The entire absence of leucocytosis made malignant disease (which would manifest itself in marked anemia) highly improbable. The high color index would exclude chlorosis, and the comparative absence of poikilocytosis and microcytosis would exclude pernicious anemia.

Thus the question of diagnosis was narrowed down to (1) secondary anemia from tuberculosis or malaria, and (2) to that comparatively rare form of disease recognized by Banti as splenic anemia or splenic pseudo-leukemia. After exhausting all available means, with negative results, I excluded tuberculosis, while repeated examination of the blood failed to discover the presence of any of the malarial organisms. By this process of exclusion, therefore, the diagnosis of splenic anemia, or splenic pseudo-leukemia was made.

The blood was examined again March 4th, and March 16th, with the following results:

Date.	Erythrocytes. (Per c.mm.)	Leucocytes. (Per c.mm.)	Hemoglobin. (Per cent.)	Color index. (Approximately.)
March 4th.	2,500,000	Not counted.	23	.72
March 16th.	2,600,000	6500	22	.7

Qualitative changes found at these examinations were in brief, as follows: Poikilocytosis, slight; very few macrocytes and an occasional normoblast present; polychromatophilia quite marked. A number of myelocytes were found, as well as a relative excess of lymphocytes; adult cells rather below normal, while no eosinophiles were present.

From February 25th to March 16th, there was much pain in the left side, referable to the area of splenic dulness, as well as persistent edema of the face and lower extremities. Labored respiration upon slight exertion was marked, and the anemic murmur was clearly distinguishable. From the 10th to the 16th of March, there was some improvement in the general condition, but the prognosis remained necessarily grave. After March 16th, I did not again see the patient until May 1st. At this time I found an apparently improved condition, anemia being less marked, although still striking, and the "fatty" appearance of the eyeball had disappeared, as had the edema of the extremities. At this time the murmur was still distinct though not quite so loud.

Upon palpation I found the spleen reduced in size, the dulness at the widest point extending to the external border

of the rectus and from the eighth rib to within one inch above the crest of the ilium.

In conclusion, I may say that though I should hesitate to give a prognosis in this case, still it is my belief that recovery is possible.

MEDICAL PROGRESS.

Fractures of the Lower End of the Radius.—KAHLEYSS (*Deut. Zeitschr. f. Chir.*, vol. xlv, p. 531), having examined and photographed with the aid of the Röntgen-rays forty-eight recent fractures of the lower end of the radius, is of the opinion that some of the widely accepted statements concerning this common injury are erroneous. Such fractures may be classed as follows: (1) Separation of the epiphysis, which occurs only in early childhood in a pure form, and in late childhood is invariably associated with fracture of the diaphysis; (2) incomplete fractures, which in the form of fissures are really far rarer than has been supposed; (3) complete fractures, which may or may not involve the whole thickness of the bone.

Fissures were found to give such slight symptoms that their diagnosis from contusions of the radius is very difficult without the aid of the Röntgen-rays. The possibility of palpating the edges of a fissure is ridiculed by the writer. Such cases are undoubtedly complete fractures. In the forty-eight cases examined a fissure was found but twice, and in both instances it was produced by a fall on the back of the hand.

Of the complete fractures, eighty-nine per cent. involved the whole thickness of the radius, while in eleven per cent. only the styloid process, or a part of the articular surface, was separated. In two-thirds of the complete fractures the break was a single fracture, and in one-third more than one fracture-line existed. Half of the single fracture-lines ran practically straight across the bone; half were oblique or (a few) irregular. In three-fourths of the cases in which more than one line of fracture existed the break was Y-shaped.

The distance of the line of fracture from the articular surface was given by Colles as 1.5 inches. Others have said that this distance is too great. The photographs showed it to be in most cases from one-half to one inch. In oblique fractures the line of break was from half an inch to an inch higher on the radial side of the bone than on the ulnar side. The radiocarpal joint was involved in forty-two per cent. of the cases.

Displacement of the lower fragment, contrary to the commonly accepted opinion, took place almost invariably upward, backward, and outward. Rotation of the fragment about its sagittal axis was very infrequent, but rotation about its frontal axis was often found. Another unexpected discovery was the frequent occurrence of fracture of the tip of the ulna. This was found to exist in no fewer than seventy-eight per cent. of all cases, and is, therefore, by far the commonest complication.

Kahleyss disputes the idea of Lecomte that fractures of the lower end of the radius are purely tearing fractures, due to strain on the bone from over-extension of the posterior carpal ligament. He agrees with Löbker that they may be caused in this manner; but he asserts, as does the latter, that they may also be caused by a direct blow on the lower end of the bone. The common cause of the typical oblique fracture, however, is a combination of these two forces, strain and blow.

A New Incision for Operation upon the Shoulder-Joint.—SENN (*Nashville Jour. Med. and Surg.*, January, 1898) has devised an incision for operations upon the shoulder-joint which he believes is an improvement upon any yet proposed. The scar resulting from the operation is well protected by the prominence formed by the acromion, and at the same time the incision allows free access to every part of the shoulder-joint and its immediate vicinity. The external incision is made so as to form an oval cutaneous flap which is turned upward, exposing the upper half of the deltoid muscle. It is commenced over the coracoid process, and is carried downward and outward in a gentle curve as far as the middle of the deltoid muscle, when it is continued in a similar curve upward and backward as far as the posterior border of the axillary space on the same level as that at which it was commenced, that is, a point opposite the coracoid. The semilunar flap is next dissected up as far as the base of the acromion process and then reflected back. The acromion process is detached with a saw and turned downward with the deltoid muscle attached. The capsule of the joint is now freely exposed. If the operation is for an irreducible dislocation, the head of the humerus may now be easily found and replaced; if it is performed in order to remove diseased tissue, the joint may be opened and its interior subjected to careful examination. It is rarely necessary to drill the bone for the placing of the sutures as a catgut suture of the periosteum is sufficient. The divided portion of the deltoid muscle is sutured separately with catgut, and the cutaneous flap is brought down in position and sutured in the usual manner. After the operation has been performed for disease of the shoulder-joint drainage is necessary for two or three days. In aseptic cases primary union should be obtained.

Complete Hysterectomy.—CHALOT (*Centralbl. f. Gyne.*, November 13, 1897) has attempted to find a method of hysterectomy which will be far more radical than the usual methods of removal, either through the vagina or through an abdominal incision. The necessary points of a perfect operation are: (1) removal of the diseased tissues in one mass by an incision wide of the new growth; (2) careful excision of all affected glands. According to the writer, these principles can only be carried out by means of a celiotomy with the patient in the Trendelenburg position, the removal of the uterus being preceded by ligation and division of the internal iliac arteries, and by transplantation of the ureters. The transplantation of the ureters may, if more convenient, follow the excision of the uterus. Either the rectum, or, in some cases, the bladder, may serve as the receptacle of the urine. These four steps of the operation constitute a new method of hysterectomy, called by the inventor, "ultra-uretera hysterectomy."

The Medical News.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 Fifth Avenue (corner of 18th St.), New York.

SATURDAY, MARCH 5, 1898.

THE LATEST FACTS ABOUT PHAGOCYTOSIS.

After the investigations of Buchner had proved beyond a doubt that both blood and blood-serum possess the power to destroy bacteria, the question of the exact nature and the origin of the substance to which the blood owed this attribute was still an open one. Buchner, Hahn, and Denys assumed the existence of an albuminous substance which they called "alexin." This they thought came from the polynuclear leucocytes, and believed that in it lay the bactericidal power of the blood. This theory enhanced the importance of the blood-serum and the lymph, and was apparently in sharp contrast to that of Metchnikoff, who asserted that the leucocytes took the bacteria into their protoplasm, swallowed them, as it were, and digested them, thus protecting the body from their pernicious influence. When it came to be recognized that alexin might come from the leucocytes, the opposition to this phagocytic theory of Metchnikoff was not so pronounced as formerly. For it was easy to suppose that the bactericidal substance which was derived from a leucocyte might be active while yet in the body of the cell. On the other hand, it is equally supposable that alexin may be produced only outside the body of the leucocyte—perhaps by its death.

This question is not yet satisfactorily settled, and several investigators have been working for its solution. Recently Schattenfroh published at length the results of a long series of experiments which he had conducted along this line. His conclusions are as follows: (1) The leucocytes of rabbits and guinea-pigs contain a bactericidal substance—at least such a substance is set free when they are destroyed. (2) The bactericidal power of this substance is not destroyed by drying the cells, nor by keeping them at a temperature of 60°C. (140° F.) for half an hour. It is lost if the leucocytes are kept at 80° to 85° C. (176° to 185° F.) for a half hour. (3) By macerating leucocytes for a short time in warm normal salt solution, or for a long time in cold normal salt solution, an extract free from leucocytes is obtained, which possesses a bactericidal power of varying toxicity for different kinds of bacteria. (4) The bactericidal power of blood and that of such leucocytic fluid are not always parallel. Nevertheless it does not necessarily follow that they are not due to the same substance. (5) Leucocytes contain, besides the bactericidal substance referred to, another body which acts in an antagonistic manner.

Lowit, by tying the aorta, was able to reduce the number of leucocytes in the blood circulating through the head and lungs. He found that when their number was less than 800 to the cubic millimeter, the bactericidal power of the blood was greatly reduced or even absent. As the polynuclear leucocytes disappeared more rapidly he concluded that they are especially potent in bactericidal power.

Jacob has found that by the use of protalbumose he can produce hyperleucocytosis, and that the blood or serum from an animal which has been thus treated, will, if injected into the circulation of another animal, enable it to withstand an otherwise fatal dose of pneumococcic infection. He hopes, therefore, to be able to exert a favorable influence upon infectious diseases by inducing an artificial hyperleucocytosis in the individual. These are some of the results of recent research in this interesting field.

THE BRUSH BILL AMENDED.

The editor of the Medical News has been favored with a personal letter from Dr. Brush, the author of the bill modifying the powers of the Board of Health, in which he assures the editor that practically all of

the suggestions made in the editorial columns of the MEDICAL NEWS of February 19th, an advance copy of which had been sent to him, have been accepted and the bill already modified in accordance therewith: The president of the Police Board is restored to membership in the Board of Health; the term of service remains six years instead of four; the office of president of the board may be filled by a physician as well as a layman, and the Mayor shall designate one of the commissioners appointed by him to be the president; the board is empowered to prepare and to preserve vaccine lymph and to produce diphtheria antitoxin and other antitoxins for the use of the department; the board is not restrained from placing pulmonary tuberculosis among the contagious diseases, nor from enforcing the regulations concerning tuberculosis recently promulgated by it.

If restraining the board from the sale of its products shall so cripple its financial resources as to curtail the lines of research which have been prosecuted with such great success, it will become the duty of the profession to see to it that necessary appropriation of the public moneys shall be forthcoming. The acknowledgment by the superintendent of the Institut Pasteur, accorded the workers in the laboratories of the Board of Health, as presented in another column, is a source of gratification, not only to the medical profession of this city but also to the entire community, and reflects credit upon those who have had the foresight to anticipate the possibility, and provide for the accomplishment, of such results.

THE REMARKABLE SUCCESS OF THE NEW YORK BOARD OF HEALTH IN PRODUCING DIPHTHERIA ANTITOXIN.

IN the MEDICAL NEWS of February 12th it was stated editorially, on the authority of the superintendent of the laboratories of the New York Board of Health, that the laboratories of this department had surpassed all others in producing a high-grade diphtheria antitoxin, and that the virulent cultures of the diphtheria bacillus from which these antitoxins were obtained had been sought by the biologic laboratories of England, France, and Germany. While no one has ventured to deny this statement publicly, it has been scoffed at in private by enemies of the department as an idle boast. It is gratifying, therefore, to find this statement confirmed and the obligation of the Institut Pasteur recognized in an article by L. Martin, chief of the laboratory of the Institut Pasteur in the January number of the *Annales de l'Institut Pasteur*.

The author gives the results of a long series of investigations in which he has carefully gone over the recent work of Park and Williams of the laboratory of the New York Board of Health (*Journal of Experimental Medicine*, vol. i, No. 1) and of Spronck (*Annales de l'Institut Pasteur*, 1895). His conclusions coincide with those of Park and Williams in all important respects. With the diphtheria bacillus sent to him by them he was able, by following their methods, to produce a toxin ten times as strong as any he had formerly obtained. He has been able to obtain no bacillus from cases of diphtheria in Paris which approaches in toxicity the one sent him from New York, and with the stronger toxin from the American bacillus Martin has been able to produce in his horses an antitoxin triple the strength formerly obtained. He finds that the bacilli grown in bouillon under a current of air, as advised by Roux and Yersin, produce toxin more quickly than when grown in the ordinary wide-mouth flasks. The increased rapidity of the production of the toxin is not sufficient, however, to compensate for the difficulties encountered in carrying out the process.

Although with ordinary nutrient bouillon rendered sufficiently alkalin Martin found strong toxin produced in the cultures with a fair degree of regularity, nevertheless, still better results could be produced with a bouillon so prepared that it contained no substances capable of producing an acid fermentation with the diphtheria bacillus. This he obtained by a special process from the pig's stomach.

Martin records the interesting fact that a diphtheria bacillus which, when injected into a rabbit, shows no virulence, may, nevertheless, produce in bouillon a strong toxin. He presents many additional points which are of interest to bacteriologists, especially those interested in the production of antitoxin.

In this article by Louis Martin there are several statements which have a bearing on the value of experimental work by public laboratories in subjects which naturally come most directly under their supervision. He states: "It is certain that with the work of Park and Williams a great advance has been

accomplished in the production of diphtheria toxin. Previous to their work toxins fatal in doses of 1/10 to 1/30 of a c.cm. had been produced, but they have obtained toxins of which 1/100 to 1/200 c.cm. is the fatal dose. The serums up to the time that I obtained the stronger toxins were of 100 units strength; now after their employment they are of 200 and 300 units strength."

Again: "It is to be hoped that serums of still greater strength will be obtained in the future from the increased activity of the toxins. This will render more easy and certain the serum treatment and permit the mortality of diphtheria to be diminished still further."

Inquiry at the research laboratory of the New York City Health Department reveals the fact that this exceedingly virulent diphtheria bacillus referred to, has been sent, free of charge, to nearly all the laboratories, both public and private, in this country, and also to England, France, and Germany.

Thus the advance accomplished at the New York laboratory in the methods of producing toxin and the bacillus there developed have markedly helped in giving to all physicians, from whatever source they may obtain it, an antitoxin of greater strength than ever before.

It should be remembered by those who feel so strongly that the sale of its surplus of antitoxin by the Board of Health of New York is a wrong to private capital, that all the money thus obtained is spent in experimental work, that it cannot be obtained otherwise, and that the results of this work are freely and entirely given out so that all may make use of them. It is only by having a number of such laboratories freely helping each other and freely giving out their information to physicians that rapid advance is possible.

THE DISPENSARY BILL.

The advocates and opponents of the bill regarding the management of dispensaries in New York State have been given a hearing before the Senate committee to which it had been referred. A remarkable feature of the argument of one opponent of the bill, who is president of one of the large dispensaries of New York City, was the statement that the underlying motive which inspires this legislation is the desire of the medical profession to increase their incomes.

The spiteful peroration with which this gentleman closed his harangue is not indicative of that cheerful and willing spirit of reform which he insisted earlier in his address characterizes the managers of all dispensaries. He said: "If this act is to go through, by all means change its title. Write it plainly: An act to prevent medical treatment at moderate rates and to permit unlimited charges by physicians. In a word, gentleman, make it an act to create a medical trust." Right here it might be well to call the attention of the wealthy managers of dispensaries to the possibility of the fact that in the sharp rivalry of the different dispensaries to increase their business, they lose sight of the primary object of the dispensary, and judge of the success of their work by the increased number of persons they have induced to seek aid at their hands. The business principle that "the larger the business the more successful the undertaking" does not hold good in charity work. The extension of the principles of paternal government, and the debauchery of the moral sense of personal responsibility in the recipients of charity—and this is what the dispensaries of New York are doing—is not a benefit to the community, but a curse.

Anent this subject the current number of the *Philadelphia Medical Journal* says: "Legal advice, groceries, clothes, and housing are as necessary to our Lord Demos as medical advice and drugs. Why then should not lawyers, store-keepers, farmers, and artisans give from one-fourth to one-half of their time and labor in free service to their fellows? The medical men have thus given of their time and lives—and what is their reward? A profession divided against itself and half of the outside world living like a parasite upon its powerless host. The idea is growing fast in the parasite's cunning mind that by playing the two factions of the profession against each other he can feed on unmolested. Astute politicians are availing themselves of this, and leading us at a rapid pace down the smooth *decensus averni* of socialistic depravity. It is clearly high time that we should turn about and painfully return to honor and self-respect, and in doing so show the world how to regain the same qualities. This is not a case of Profession *vs.* The People—but it is a case of the people against itself."

ECHOES AND NEWS.

A New Disease in the Klondike.—It is said that cerebro-spinal meningitis is epidemic among the gold-seekers in Alaska. The disease is rapidly fatal.

Water Purification by Electricity.—An association has been formed in Paris to exploit the new method of purifying water by means of electricity. This process has been endorsed by Drs. Tyndal and Roux.

Resignation of Professor Esmarch.—Professor Esmarch of the University of Keil is about to resign the chair of surgery, which he has occupied since 1857. Professor Esmarch is seventy-five years of age.

New York Will Pay for Tuberculous Cattle Destroyed.—The bill authorizing the Board of Health of New York City to pay for cattle destroyed because of tuberculosis has been passed by both branches of the Legislature.

Bombay Hospital Destroyed by Fire.—One of the plague hospitals at Bombay was destroyed by fire on February 19th. Twelve European and eighty-four native patients were saved. Three patients died from shock.

Soldiers Vaccinated.—All the soldiers at Fort Ethan Allen, at Essex Junction, Vermont, have been ordered to be vaccinated at once on account of the possibility of being ordered to Cuba where smallpox is prevalent.

A Correction.—In Dr. Gallant's article on "Inguinal Hernia," which appeared in the MEDICAL NEWS of last week, acknowledgment should have been made for the illustration, which was obtained through the courtesy of *Mathew's Medical Quarterly.*

Faithfulness of Surgeon Honeberger.—The day-book of the chief medical officer of the cruiser "Maine" has been recovered from the wreck. It bears witness to the methodical habits of Surgeon Honeberger, for the record was brought up to the last moment before the wreck of the ship.

Vigilance at Quarantine.—A vessel has just arrived and is being detained at quarantine in Pensacola, Florida, from Para, Brazil, bringing the report that while the vessel was at Para the captain's daughter and six of the crew were attacked with yellow fever and sent to the hospital at that place where they all died.

The Senn Medal.—Those members of the American Medical Association who intend to compete for the medal offered by Dr. Nicholas Senn for the best essay on some surgical subject are requested to forward the typewritten copies of contributions to J. McFadden Gaston, M.D., Atlanta, Ga., immediately.

New York Climate too Severe for Eskimos.—One of the band of Eskimo which accompanied Lieutenant Peary's expedition on its return from the North, recently died of pneumonia at Bellevue Hospital. All of the party have suffered from colds of varying severity, and at one time four of them were under treatment for this disease.

Degeneracy in Russia.—The Russian *Novoye Vremya* complains of the degeneracy of the present inhabitants of the great Empire and attributes it to the lack of proper nourishment. It declares that the lower class have one-third less to eat than their grandparents had and they are proportionately suffering from the lack of other essentials of life.

American Neurological Association.—The Council announces that the Twenty-four Annual Meeting of the Association will be held in New York at the Academy of Medicine on Thursday, Friday, and Saturday, May 26, 27, and 28, 1898. There will be two sessions daily, one from 10 A.M. to 12.30 P.M., the other from 2 P.M. to 4.30 P.M.

Bill to Prohibit the Practice of Faith-Cure.—A bill is in preparation which so amends the New York health laws with regard to the practice of the healing art as to prevent practice by persons who profess to cure by mental processes alone. The direct antithesis of this measure has appeared in the form of a bill incorporating osteopaths. The article called eternal vigilance was never in greater demand.

Important Work of the United States Department of Agriculture.—The United States Senate has authorized the immediate publication of a second edition of Bulletin 19 of the Bureau of Animal Industry on "The Inspection of Meats for Animal Parasites." This bulletin was issued on February 8, 1898, and has been in such demand that at present it is impossible to obtain a copy. Physicians desiring copies of the second edition should address their Congressmen or Senators.

Removal of the Stomach.—A correspondent writes to the *Medical Press and Circular* (London) stating that Dr. Schlatter's recent removal of the stomach is not the first case of the kind on record, for the operation had already been performed by Professor Maydl. The patient survived and was alive and well six years after the operation. The case is reported in full in the *Wien. Med. Woch.*, August 26, 1896, and is briefly mentioned in the *British Medical Journal*, Epitome, ii, No. 323, 1896.

The Post-Graduate Must Reinstate Professor Kelsey.—Professor Charles B. Kelsey has received from the Supreme Court a peremptory writ of mandamus directing the Board of Directors of the New York Post-Graduate Medical School and Hospital to reinstate him as a professor of that institution. Dr. Kelsey was dismissed without a hearing by a majority vote at a meeting of the board which was not attended by all the members. The Court decided that this was illegal, as it requires a majority of the entire board to dismiss a member of the faculty.

Home for the Treatment of Incipient Tuberculosis.—The Working Girls' Vacation Society of New York City has established at Santa Clara, Franklin County, N. Y., a

vacation house for the treatment of incipient cases of pulmonary tuberculosis, occurring in unmarried working girls. There is a resident woman physician, and a complete equipment for the modern management of this class of cases. The altitude is about 1700 feet. The price per week is $7, which covers all expenses except laundry. All persons applying for admission should be referred to the medical director of the Society at 222 West Thirty-eighth street, New York City.

Pasteur Institute at Constantinople.—The bacteriologic laboratory which was founded by Pasteur at Constantinople by request of the Sultan has recently re-opened its doors after a long period of idleness due to the incompetency and carelessness of the State officials and to lack of funds. The French *chargé d'affaires* protested, as did the Imperial Society of Medicine, and in this way the attention of the Sultan was drawn to the precarious state of an institution in which he had taken the greatest interest. It is probable that the work of the institution will be greatly developed, for orders have been given that the director of the institute shall want for nothing.

Osteopathy in the State Legislature.—There is some consolation in the reflection that only about one-tenth of all the bills introduced in the State Legislature are enacted into law. A bill known as Assemby Bill No. 939, entitled "An Act Regulating and Legalizing the Practice of Osteopathy in the State of New York," has recently been introduced at Albany by Mr. Raplee. A similar bill was introduced this winter in the Legislature of Illinois, but it met with such a torrent of protest from the medical profession that it was promptly defeated. A few hundred letters of remonstrance addressed to Mr. Raplee, the author of the present bill, would probably consign this measure to a worthy fate.

Dr. McGraw of Detroit Sued for Malpractice.—A patient of Dr. Theodore A. McGraw recently brought suit against the Doctor in the Wayne Circuit Court for $5000 damages for malpractice. The plaintiff averred that during May last he was suffering from acute pain in the right leg caused by osteitis of the tibia, and employed the Doctor to operate upon it and remove the diseased portions of bone; that the surgeon made a mistake and operated upon the tibia of the left leg. These facts are true except as to the "mistake." After the patient had been anesthetized, the doctor found that both legs were similarly affected. He asked which one he was to operate upon, and the patient's father replied that it was the left leg. The surgeon acted upon the decision of the father and operated upon the left tibia. The judge decided that the Doctor had a right to rely upon the decision of the father of the plaintiff in this matter, and directed the jury to find a verdict for the defendant.

The Cause of Yellow Fever.—In our Berlin letter of this week it will be noted that the trend of German medical thought does not seem inclined to accept as final Sanarelli's declarations as to his discovery of the bacillus of yellow fever. Our foreign correspondent mentions German conservatism as a reason for this skeptical way of regarding Sanarelli's alleged discovery. It is indeed lamentable that the Germans are not as ready to employ their almost wonderful critical acumen in the discussion of "German discoveries" as they are those of France, Italy, and even those of benighted America. As an example we might mention Pasteur's work on rabies, which, we learn, they are only beginning to recognize as having something "in it." Bacteriologic science has not as yet accepted Sanarelli's discovery as the proven cause of yellow fever, but at the same time we see no good reason for deserting Sanarelli for a yeast and mold—the latter having been put forward as the possible etiologic factor of yellow fever.

Resolution.—The following resolution, offered by Dr. J. H. Burtenshaw, was passed, with but one dissenting vote, by the Medical Society of the County of New York at a very largely attended meeting held February 28th: "*Resolved*, That the Medical Society of the County of New York reaffirms its indorsement of the bill to amend the State Charities Law, relating to the Licensing and Regulation of Dispensaries by the State Board of Charities, now before the Legislature of the State, and that it urges the immediate passage of the bill in its present form. *Resolved*, That this resolution be signed by the president and secretary of this society, and that copies be forwarded to the Lieutenant-Governor, the Speaker of the Assembly, and the chairmen of the Committees on Public Health of the Senate and Assembly." This action clearly demonstrates the position taken by the largest medical society in the State with regard to the Dispensary Bill, and should once and for all put an end to the unreliable statements which have been spread broadcast of late regarding the sentiment of the profession in New York City in opposition to the measure. Similar action has been taken also during the past week by the Medical Society of the County of Kings, the New York County Medical Association, the New York Medical League, and the Committee of the New York State Medical Association.

Bulletin of the Chicago Health Department.—For nearly two years the Department of Health of Chicago has been investigating the claims made for formaldehyd as a disinfectant, with especial reference to its value for household or domestic disinfection. The results have been so satisfactory and the remarkable bactericidal properties of formic aldehyd have received confirmation in such a practical manner through the experiments made that at the suggestion of Dr. Reilly, assistant commissioner, an inexpensive vaporizer has been devised for use in the room occupied by a diphtheria patient. This vaporizer consists of a shallow cup supported over an ordinary cheap lamp, such as is made to burn kerosene. Methyl alcohol is used for the flame. The cup is nearly filled with a solution consisting of about one part of a forty-per-cent. formalin solution and five parts of boiling water. The flame is so adjusted as to keep the solution just at the boiling-point. The device in use costs less than 20 cents. Twenty-one deaths from influenza occurred in Chicago during the month of January, 1898, as against a total of fifteen for

the entire year of 1897. The epidemic of influenza was the chief factor in increasing the total number of deaths from 21,897 in 1890 to 27,754 in 1891—an increase of more than one-fifth. A return of the disease is very much feared. The health commissioner has called attention to the fact that influenza is a germ disease and, therefore, contagious. He advises that people "keep out of the way of contagion," by which is meant, among other things, avoiding close contact with one suffering from the disease, not sleeping in the same room, much less in the same bed, with such a sufferer, and not using any article or utensil in common with him.

Obituary.—Dr. Edward C. Seguin died of cirrhosis of the liver on February 19th at his home in New York City. Dr. Seguin was born in Paris, France, in 1843. He was the only child of Dr. Edouard O. Seguin, who, with his family, came to the United States in 1850 and settled in Cleveland, Ohio. In 1861, then residing at Mount Vernon, N. Y., young Seguin began the study of medicine with his father, attended three courses of lectures at the College of Physicians and Surgeons, New York, and was graduated in 1864. Meanwhile Dr. Seguin had entered the medical department of the army. He was appointed a medical cadet in the regular army and served two years, until August, 1864. Later he was assigned to duty at Forts Craig and Seldon, New Mexico. During the winter of 1869–70 Dr. Seguin studied in Paris under Brown-Séquard, Charcot, Ranvier, and Cornil, and has since made the treatment of nervous diseases a specialty. In 1871 he became a member of the Faculty of the College of Physicians and Surgeons, and lectured in this institution on diseases of the spinal cord and on insanity from 1871 to 1885. In 1873 he founded the clinic for nervous diseases. He was one of the founders of the American Neurological Association and of the New York Neurological Society. He was also a member of the New York Pathological Society and of many medical societies of this country and of Europe. In 1894 his health began to fail, and he gave up professional work in July, 1896. To the New York Academy of Medicine Dr. Seguin bequeathed an oil painting of his father, Dr. Edward Onesimus Seguin; an autograph letter from Pope Pius IX., dated December 16, 1847, in which his Holiness compliments Dr. E. O. Seguin for his work in ameliorating the condition of imbecile children; a bronze medallion of Charcot, which was presented to him by the renowned French master, and a large portrait of Brown-Séquard. To the Academy he also left the greater part of his library. All his instruments and appliances for the study of the nervous system, all his pathologic specimens and part of his library, he gives to the pathologic laboratory of the Alumni Association of the College of Physicians and Surgeons, to be set apart and specially catalogued, and not to be permitted to leave the laboratory. If the association will not accept the charge and the conditions, the bequest is to go to the Academy of Medicine under the same conditions.—Dr. Charles Jasper Bickham recently died of heart disease at his residence in New Orleans, La., in his sixty-eighth year. Dr. Bickham was born near Covington, La., in 1830, and was the son of a prominent planter. He was educated at an institution in Texas, which subsequently became the Southwestern University. After four years' study he received the degree of Master of Arts. He graduated in medicine in 1856, and was soon after appointed Assistant House Surgeon at Charity Hospital, New Orleans, which position he filled with distinction until 1859. Dr. Bickham was demonstrator of anatomy in the Louisiana Medical College from 1867 to 1872. In 1894 he was appointed a member of the Board of Health, and served until 1896, when he resigned on account of ill health.—Surgeon Thomas B. Bailey, Passed Assistant Surgeon of the United States Navy, was found dead in his room at a hotel in Washington, D. C., February 24th. He left a letter providing for the distribution of his effects and expressing the fear that he was about to die from heart disease. He had just returned from a tour of duty in China, and had been appointed to duty at the Washington Navy Yard.—Dr. John P. Maynard died at the age of sixty-two years at his home in Dedham, Mass., February 26th. He was born in Boston, and was a graduate of Yale College and the Harvard Medical School. Dr. Maynard was the discoverer of collodion, and suggested its application in surgery.

CORRESPONDENCE.

MIDWIVES.

To the Editor of the Medical News.

Dear Sir: Dr. Henry J. Garrigues' article on "Midwives," in your issue of February 19th, page 232, is strangely inaccurate in the opening paragraph. I was the author of the bill mentioned by Dr. Garrigues, and before reading it at a meeting of the Medical Society of the County of New York I consulted the president of the society, Dr. S. O. Van der Poel, and Drs. Abraham Jacobi, Paul F. Mundé, Allen S. Church, Alfred L. Loomis, Cornelius R. Agnew, John L. Campbell, and others, all of whom were in favor of the bill. The bill in question proposed the establishment of a school of midwifery in connection with a maternity hospital, where the pupils would receive instruction in anatomy, physiology, and obstetrics under the best professors, and, before being graduated, be obliged to attend cases of obstetrics under the supervision of competent physicians, and then receive instruction in asepsis, antisepsis, and hygiene.

It was intended that this school should be entirely under the control of medical men. The board of managers (medical men) were to appoint the professors and to have general supervision of the school and hospital. I read the bill at a stated meeting of the Medical Society of the County of New York during the administration of Dr. S. O. Van der Poel. After a short discussion it was referred to the Commitia Minora of the Society, and the next stated meeting was appointed for its discussion. The Commitia Minora reported adversely upon the bill, and after a long and somewhat heated discussion, in which Drs. Jacobi, Mundé, Church, and others, spoke in favor of the

proposed measure and many professors of medical colleges against it, the society voted in the negative.

Before submitting my bill to the judgment of the Society, I had stated that if the Society did not approve I would do nothing more about it. The Society disapproved, and I locked the bill in my desk. It was never sent to Albany; it was killed in the County Medical Society. Queerly enough, the great objection brought against my bill was that graduates of the proposed school would be better instructed in obstetrics than those of the regular medical colleges.

With regard to any other bill introduced in the State Legislature, I know nothing.

PALMER C. COLE, M.D.

254 WEST FORTY-SECOND STREET,
NEW YORK, February 27, 1898.

"CHARITY ABUSES IN MICHIGAN."

To the Editor of the MEDICAL NEWS.

DEAR SIR: Under the above heading in your issue of February 19th will be found the following: "In Michigan the abuse referred to seems especially rife in the free dispensary of the University Hospital at Ann Arbor, and it is against this institution that criticism is particularly leveled." The above statement is in part false, and, I suppose, in part true. The statement that charity abuse is especially rife in the University Hospital at Ann Arbor is false. The other part of the statement, that criticism is particularly leveled at this institution, may be true. The facts in the matter are, briefly, these:

In 1883 the Board of Regents of the University of Michigan made a by-law excluding from the University Hospital all people who were able to pay for medical services. This by-law has been, and is, enforced. Some months ago, a well-to-do individual appeared at the hospital and demanded admission on the ground that he was a taxpayer and contributed to the support of the institution. His request was refused. He appealed to the Board of Regents. The Board laid his protest upon the table, and the old rule remains in force. Abuse of public charity in the hospital at the University of Michigan has never been great.

Respectfully,

VICTOR C. VAUGHAN, M.D.

ANN ARBOR, February 24, 1898.

THE DISPENSARY BILL: A REPLY TO DR. VAN FLEET.

To the Editor of the MEDICAL NEWS.

DEAR SIR: I ask the courtesy of the use of your columns in order to reply to certain of the statements contained in Dr. Frank Van Fleet's letter on the subject of the Dispensary Bill, printed in the MEDICAL NEWS for February 19th.

The so-called Joint-Committee Dispensary Bill, now before the Legislature of the State, embodies the result of many months of careful investigation by the committee having it in charge. It has been approved by the representatives of the great medical schools who were designated by the faculties of these schools to serve on the several committees, and has received the unqualified indorsement of the Medical Society of the County of New York, Medical Society of the County of Kings, Medical Society of the County of Queens, Medical Society of the County of Richmond, New York State Medical Association, New York County Medical Association, New York Medical League, New York Society for Advancing the Practice of Medicine, Kings County Medical Association, Brooklyn Medical Society, Brooklyn Medical Association, and the Long Island Medical Society, all incorporated bodies, and representing a membership of more than 5,000 reputable physicians of the State. It certainly is to be sincerely regretted that, according to Dr. Van Fleet's letter, the bill has not called forth the hearty support of the Committee on Legislation of the Medical Society of the State of New York, composed of *three* members!

The Medical Society of the State of New York, at its recent annual meeting at Albany, took no official action whatever in favor of, or against, the bill. The delegates to the Society from the county medical societies of New York, Kings, Queens, and Richmond were specifically instructed by unanimous vote of their several societies to vote in favor of indorsement of the bill, and there can be no doubt that it would have been so indorsed by the State Society had it not been decided at an informal conference of certain of the members that its consideration would interfere with the scientific work laid out for the meeting. Official confirmation of the fact that the bill was not acted upon during the meeting is contained in the subjoined copy of a letter recently received from the Secretary of the State Medical Society:

ALBANY, N. Y., February 12, 1898.

DEAR DOCTOR: In reply to your letter of inquiry just at hand as to whether the matter of the so-called Dispensary Bill was brought before the Medical Society of the State of New York at its recent meeting, I would say that it did not come up in any way whatever; it never was referred to in any way throughout the entire session. The Anniversary Address contained some reference to the topic of free dispensaries, but no action was called for or taken on it.

Yours very sincerely,

F. C. CURTIS,
Secretary.

17 WASHINGTON AVENUE.

The By-Laws of the State Medical Society (page 17) specify the duties of its Committee on Legislation as follows, the italics being my own:

There shall be a standing Committee on Legislation, consisting of three members, the duty of which shall be to watch the course of State legislation on medical subjects, and *to take charge of such matters pertaining to medical legislation as shall be referred to it by this Society.*

In spite of the fact that no official action was taken by the Society in connection with the Dispensary Bill, and that, in consequence, the bill was not referred to the Society's Committee on Legislation, the Chairman of that Committee, Dr. Van Fleet, has issued letters to the lay and medical press, as well as to many members of the profession at large, attacking the bill. To these letters, in addition to his name, he has appended his official title, and the impression is thus conveyed that their issuance

has been authorized by the State Medical Society, and that they officially reflect the opinion of its members. On the contrary, these communications from the Chairman of the State's Society's Legislative Committee do *not* represent the opinion of the Society, their publication was *not* authorized, and the only inference that can be drawn is that they were published over the gentleman's official title with plain intent to mislead public opinion.

Dr. Van Fleet says in his letter to the MEDICAL NEWS: "You are mistaken if you think the Chairman of the Legislative Committee of the Medical Society of the State of New York is the only person opposed to the measure under consideration, for my action is indorsed by the whole committe, by the officers of the State Society, and by the majority of the medical men of the State." By the whole committee—of *three* members, of which Dr. Van Fleet is one! By the officers of the State Society —*four* in number! By the majority of the medical men of the State! The latter is a modest assertion, but Dr. Van Fleet fails to offer proof of its accuracy. Apparently the publicly recorded indorsement of the Bill by twelve of the largest and most influential medical societies of the United States carries no weight with this gentleman in comparison with the opinion of the solitary seven. "It is safe to say that not one-fourth of the profession of the City of New York would indorse this bill if its true character were known." Dr. Van Fleet probably does not know, which is very unfortunate, that during the past week, after plenty of time for mature reflection, five of the societies which originally indorsed the bill unanimously reaffirmed their indorsement, and in no uncertain tone either, one being the Medical Society of the County of New York, of which Dr. Van Fleet is a member.

Every argument brought forward by Dr. Van Fleet is amply refuted by the reports of the State Board of Charities for the years 1896 and 1897, and by those to the Medical Society of the County of New York of its Committee on the Abuse of Medical Charity, transmitted May 24 and December 27, 1897. The simple truth of the matter is that the Boards of Trustees of a majority of the large dispensaries located in this city, and certain physicians officially connected with these institutions, though well aware of the enormous amount of medical charity abuse which exists, have no desire to correct or control it. Their reasons for this are sufficiently obvious and need not be discussed at this time. The gross mismanagement of dispensaries in the City of New York has been a public scandal during the past twenty years, and yet in but one or two isolated instances has an attempt been made by the officials in charge to reform the abuses. It is only now, when a conscientious and determined effort is being made by the great medical societies to have all dispensaries placed on a plane with other incorporated institutions, and thus answerable to the proper authorities for the employment of appropriations and trust funds confided to their charge, and to make them subject to rules and regulations which will exclude the hordes of unworthy well-to-do applicants from the benefits of free treatment, that the cry is raised that if additional power is conferred upon the State Board of Charities every dispensary will be forced to suspend its operations, and great suffering will be entailed, in consequence, upon the deserving poor.

It is not the wish of those active in the present movement that even *one* dispensary now existing shall be closed, provided it treats only those applicants worthy of receiving free medical and surgical aid. There is no charity so beneficent, so far-reaching, or so freely bestowed as true medical charity, and so long as illness and misery exist just so long will the poor be welcomed to the institutions organized to alleviate their distress, and so long will doctors gladly minister to them. It is because thousands and tens of thousands of unworthy persons are treated at these free dispensaries every year without the slightest effort being made to investigate their claims of poverty that reform in management is demanded. The State Board of Charities is a constitutional body appointed by the Governor and confirmed by the Senate. During the past thirty-one years, or since its original institution, all matters under its jurisdiction have been managed intelligently, discretely, and with complete fairness. If the present Bill becomes a law it is the intention of the board to hold public meetings to which all interested in the subject of improvement of dispensaries will be invited, and suggestions as to the formulation of proper rules and regulations will be received and acted upon.

In conclusion permit me to say that in spite of the assertions of the Chairman of the Legislative Committee of the Medical Society of the State of New York and his committee of two, it is perfectly safe to assert that fully ninety-seven per cent. of the physicians of the City and State of New York favor the passage of the Dispensary Bill, and that the committee having it in charge will continue to receive the same cordial and hearty support which has been freely offered it since its labors began nearly two years ago.

Very truly yours,

JAMES HAWLEY BURTENSHAW,

Chairman of the late Committee of the Medical Society of the County of New York on the Abuse of Medical Charity.

128 WEST EIGHTY-SECOND STREET,
NEW YORK, February 28, 1898.

OUR BERLIN LETTER.

[From our Special Correspondent.]

THE MEDICO-LEGAL STATUS OF A HERMAPHRODITE, AND THE QUESTION OF SEX IN SUCH CASES—A BERLIN METHOD FOR THE SUPPRESSION OF QUACKERY —THE ETIOLOGY OF YELLOW FEVER AND YEASTS AND MOLDS—ALGIERS AS A WINTER-RESORT.

BERLIN, February 24, 1898.

APROPOS of the presentation before the last meeting of the Berlin Medical Society of a very perfect specimen of the genus hermaphrodite, who is on exhibition at one of the museums here, there was a discussion by some of the leaders of medical thought on the determination of sex in such cases. It is usual for the general public to think that a doctor can settle this question without difficulty. Experience, however, has shown that there can be few more tangled Gordian knots presented for unravelment

than this same question of the determination of sex in certain doubtful cases.

Among others Virchow, who had made a careful examination in this case, said that he was free to confess that he could not tell to which sex the individual belonged. Even when such cases come to autopsy it is extremely difficult to decide whether the sexual organs found are ovaries or testicles, and, of course, on these organs depends the essential distinction of sex. Not alone is it difficult to decide macroscopically, which can easily be imagined from certain gross similarities of the organs, but even microscopically it is not always easy to find distinctive sex elements with absolute assurance.

The organs are most often ovaries in such cases, but the anomalous development which has affected the rest of the urogenital system usually has had its effect on them too. Much more connective tissue than is normal is present, and in the midst of this luxuriant connective tissue often the most patient search is required to reveal the presence of sexual elements. Often, too, there would seem to be even in the ovaries or testicles themselves a certain dubiousness of structure—an amphoteric condition—as if Nature herself had not quite decided which sex was to result. Perfect sexual elements of both kinds are not to be found, but there seems to be embryonic rudiments of both in an arrested early stage of development.

Professor Landau discussed the question from the practical standpoint of a man, who, within the last year, has been called upon to decide for legal purposes the question of sex in a dubious case. He very candidly said that lawyers and judges generally share the lay opinion as to the doctor's, and especially the gynecologist's, perfect capability of deciding this question, in which opinion they are, of course, often completely at fault. The ordinary external examination may be utterly deceptive, and the combined internal and external examination may give absolutely no sure grounds upon which to determine the question of sex. One may have under one's fingers the essential sexual organs, and yet be able to tell nothing about them. "Even if we have the opportunity," he adds, "to perform an operation and so obtain microscopic specimens, we still may not be able to decide the question, and no less an authority than Professor Virchow supports us in this conservative opinion."

In these doubtful cases, according to Professor Landau, the following practical rules are the best guide: The parent must decide, in very doubtful cases, what sex will be most convenient in rearing the child. The individual must decide for him or herself at the age of eighteen years whether he or she is to continue to be considered as belonging to that sex or not, and act accordingly. There is no country in Europe, except Russia, in which such a procedure would be contrary to law. In Russia the individual would have no legal status if he or she decided to belong to a sex different from that in which their declaration of birth was made.

In the case in which Professor Landau's opinion was asked, the individual had been brought up as a girl. At the age of four years the supposedly enlarged clitoris, at the base of which the urethra opened, was removed, because its development was looked upon as pathologic. At the age of eighteen years, however, the individual decided that he was a male. His voice, his beard, his general external appearance, and, above all, his sexual feelings were those of a man. Owing to the occasional occurrence of sexual perversion, this last is not absolutely decisive in the matter, yet in very doubtful cases it is the most trustworthy factor.

The external appearances, beard, voice, form, etc., may be deceptive, as they were in the case presented before the Society. She dresses in trousers and coat, wears a beard, and in general looks like a man of low stature. Her hips and buttocks are distinctively feminine, however, and her sexual inclinations are toward men. She claims that the sexual organ on one side is a testicle, while that on the other side is an ovary. Her opinion would have been laughed at, only that a Röntgen-ray photograph of her pelvis (which is characteristically feminine) and her femora brought out a remarkable fact. One of her femora was masculine, the other feminine in type, *i. e.:* one had the obtuse angle between the neck and shaft of the femur usually noticed in men; the other the almost right angle found normally in women. This is, perhaps, the first time that this fact has been noted in such a case, and is but another proof of the profoundly fundamental nature of the disturbance of development of the normal sexual being which underlies the hermaphroditic condition.

Some time ago a prominent German medical journal published the results of its investigation of Count Matter's so-called electrohomeopathic treatment, a much advertised method of treating all the ills to which flesh is heir, and a few others besides. Needless to say it was pronounced a humbug.

The investigation was a serious one. With us in America, however, beyond the publication of its results in a few medical journals, bringing to medical men a knowledge they might easily be presumed to have beforehand, nothing would be hoped for from it. Here the Police Commission took official cognizance of it, and formally announced in a circular which must be displayed in all drug-stores, that "the treatment in question has nothing to do with Hahnemann or his disciples, and is to be considered utterly worthless." The effect of such a circular is obvious. It is the proper method of treating a fraud. If in other matters police authority steps in to prevent swindling, *i. e.:* the pretence of selling something which is not delivered to the purchaser, why not in this also? Perhaps it is only in matters concerning the health of the people that deceit in buying or selling is not cheating.

The announcement of the discovery of the yellow-fever germ naturally attracted a good deal of attention here. Generally, however, opinions as to the absolute accuracy of the supposed discovery have not that air of certain assurance with which the announcement was welcomed in other quarters. While honors of various kinds have flowed in upon Professor Sanarelli from the French, and especially from his Italian compatriots, very little has been said of his work in Germany. Of course, one obvious

reason for this is that Germany, as a nation, is very little interested in yellow fever; another and very important reason is, however, that further confirmation will have to be forthcoming before German conservatism will accept the discovery as final. It has been pointed out here that during the course of yellow fever many of the intestinal bacteria take on special characteristics; the bacterium coli, for instance, becomes especially virulent and even more proteiform, if possible, than before. The possibility of one of its varieties being considered specific for the disease, even after careful investigation, is not easy to eliminate. As the disease itself does not spread to animals, manifestations of pathologic conditions produced in animals can have very little weight. In animals the characteristic course of the disease is not reproduced, and so one of Koch's great criteria falls to the ground. One manifestation of the uncertain state of German opinion in the matter is the publication last week in a prominent medical journal here of an article from Rio de Janeiro in which a yeast and a mold are described as occurring in twenty-five bodies of yellow-fever patients, though not to be found in other bodies examined at the same time. While it would seem probable that there is in these cases some fault in the technic, recent work on pathogenic yeasts and molds shows that the possibility of human infection from these sources cannot be entirely eliminated.

Professor Fränkel, the distinguished laryngologist here, and director of the throat and nose department in the Charité, has just spent some time in Algiers. His recent report to the Society for Internal Medicine as to its extremely favorable climate and condition for a winter-resort attracted a great deal of attention. The climate of Algiers is warmer than that of the Riviera—as snow and frost are unknown, and there is less dust than in the cities along the northern shore of the Mediterranean, though it is confessed that occasional dust storms and frequent inconvenience from this source are disadvantages of the place. In Algiers itself the climate is moist as well as warm, and one is scarcely ever without sensible perspiration. At Biskra, only a few hours inland, it is so dry that one never perspires sensibly. Moisture on the skin is carried off at once in the air, which has very little humidity. There is then, within a short distance of each other, the two varieties of climate in regard to which it is so difficult to decide in any individual case of tuberculosis; whether the one or the other will be of benefit. Many consumptives improve in an extremely dry climate, but it is equally true that many do not; on the contrary, the condition is made worse. One has in Algiers a good opportunity to allow the patient to select for himself the place which seems to suit him best without the necessity of traveling a long distance.

In recent years some excellent arrangements, according to Professor Fränkel, for the care of patients have been made. There is not, moreover, the temptation to abuse his strength that some of the social obligations of the Riviera involve. As Algiers is also French territory, German opinion with regard to it is not dictated by the wish to avoid sending patients to France.

Berlin.

BRONCHIECTASIS IN A VERY YOUNG CHILD — COMPENSATORY-EXERCISE THERAPY OF TABES.

AT a meeting of the Medical Society, January 5th, VIRCHOW and HEUBNER exhibited a case of *bronchiectasis in a very young child.* The child came from a family in which disease of the lungs was common. As an infant it had had a severe intestinal catarrh, and often suffered from bronchitis. After an attack of pneumonia there developed a well-marked bronchiectasis, especially of the left side. The sputum was repeatedly examined for tubercle bacilli, but none were found. After this condition had continued several months the child developed measles, and upon recovery from this tubercle bacilli were found in the sputum. A fatal termination followed within a short time. Examination of the lungs showed a long-standing and well-marked bronchiectasis, the left lung being almost wholly destroyed and containing numerous cavities. There was, as well, tuberculosis, evidently of short duration, as none of the lesions were far advanced and none of the cavities were of an ulcerative character. Heubner again mentioned his belief that bronchiectasis frequently follows whooping-cough and measles in young children, and that if the child recovers from the respiratory disease, the bronchiectasis, if of a slight degree, may entirely disappear. He raised the question whether bronchiectasis in adults may not in most cases be traced to some such trouble in childhood.

VIRCHOW said that the case was particularly interesting to him as showing the very large amount of tissue which might be involved in the affection under consideration. In the left lung scarcely a trace of the parenchyma remained. In true bronchiectatic cavities, such as those presented in this case, the epithelium may be recognized even to the ends of the tubes.

BAGINSKY said that the occurrence of bronchiectasis in children is undoubtedly more frequent than is usually supposed. Whooping-cough is especially likely to be followed by this disease, although it may result from any form of chronic bronchitis or bronchopneumonia. He also mentioned an instance in his own practice in which a boy contracted whooping-cough at the age of four years. The disease was followed by a chronic catarrh of the bronchi, and this in turn gave rise to bronchiectasis. At the age of ten years the child developed tuberculous peritonitis and died.

At the Union for Internal Medicine, January 3d, EULENBURG spoke of *compensatory-exercise therapy in tabes*, as proposed by Fränkel. He disputed the claim, advanced by Jacob, that special apparatus is necessary to obtain good results, claiming that materials found in every house are quite sufficient.

ZABLUDOWSKY, while not disputing the advantages of this method of treatment, said that certain cases are too severe to expect good results from it alone, but that massage and exercise therapy should be combined. If this plan is systematically carried out with proper intervals of

rest, even in the most desperate cases there is a steady gain.

GOLDSCHEIDER said that the principle underlying this treatment is so simple that it could readily be applied by any physician, which, for the patient, is a far better plan than handing the treatment over to a specialist. He, too, objected to the use of complicated apparatus, which, he said, was not in the least necessary.

VON LEYDEN said that by means of this mode of treatment the therapy of diseases of the spinal cord had been lifted out of the rut in which it had been so many years. He said that the theory that tabes is a syphilitic disease has never been proved, and that the good results which sometimes follow the use of mercury are accidental. Exercise therapy, on the other hand, marks a distinct advance in treatment. The exercises reach the whole disease. While a special apparatus is not necessary, still treatment with such apparatus is found to be more exact, and the results will, in consequence, be somewhat better with than without it.

KANN-ŒYNHAUSEN said that there was no record that massage alone, or Swedish movements, had ever proved beneficial in a case of tabes. Swedish movements are directed toward the muscles, while the exercise therapy, recommended by Fränkel, is an exercise of the nerves. A tabetic person can exercise his muscles for a long time without becoming tired, while the exercises toward a definite end, as recommended in this treatment, soon weary him, thus showing the difference between the two. An apparatus does good in keeping up the interest of the patient in his treatment.

JASTROWITZ said that in this connection the influence of suggestion should not be forgotten, and, again, it is interesting to note that tabetic patients, who have become maniacal, have almost entirely lost their ataxia.

London.

ADHERENT PERICARDIUM—OBSTRUCTION OF LABOR BY OVARIAN TUMORS IN THE PELVIS.

At a meeting of the Medical Society, held January 10th, BROADBENT discussed *adherent pericardium*. An absolute diagnosis of this condition can rarely ever be made; for the symptoms are merely those of embarrassment and dilatation of the heart such as occur in all forms of cardiac disease. The physical signs upon which most weight can be placed are as follows: (1) arrest of the normal respiratory movement seen in the epigastrium; (2) imperfect descent of the apex beat during inspiration; (3) absence of shifting of the apex beat with changes in the position of the patient. However, none of these signs necessarily implies the presence of adherent pericardium. Pulsus paradoxus and pulsation of the veins have been described as frequent symptoms, but Broadbent has rarely observed them. In one case there was pulsation of a vein in the anterior chest-wall, due to the fact that the internal mammary artery had been caught by adhesions so that the blood could pass through it only when the heart was in a state of systole.

DOUGLAS-POWELL said that such cases should be divided into two groups: those in which merely the opposing surfaces of the pericardium are adherent, and those in which the external surface of the pericardium is adherent to the mediastinal tissues. In the latter, the action of the heart is interferred with to a greater extent, since it is working in a tough, fibrous, and adherent casing. In these cases the stress falls chiefly on the right side of the heart, which faces the unyielding anterior wall of the thorax. In a case recently under his observation, occurring in a girl ten years old, there had been a double-mitral-murmur, great hypertrophy, systolic depression of the first, second, and third intercostal spaces near the sternum, and systolic depression of the fifth, sixth, and seventh intercostal spaces outside the left nipple line, and a long thrusting apex beat which did not shift with respiration or with change of position. At the autopsy, both internal and external pericardial adhesions were proved to be present. Retraction at the apex, pulsus paradoxus, and epigastric pulsation, were all absent.

EWART said that simple bands of adhesion about the apex had little clinical significance, and it is probable that a universal adhesion of the pericardial membrane, without thickening, does not seriously hamper the cardiac movements. He disagreed with Douglas-Powell that the right side of the heart suffers more than the left from the presence of pericardial adhesions, and maintained that the left heart, because of its normally greater mobility, is the portion that is chiefly affected.

LEES said that in cases in which there is cardiac disease the effect of the adhesion is to fix and render permanent the dilatation which is part of the original inflammation of the heart. He had noticed a sudden dilatation of the heart during a first attack of rheumatism in children and young adults. If pericarditis occurs it fixes and renders permanent this dilatation.

In closing, BROADBENT stated that clinical observation clearly shows that the right ventricle is more embarrassed by adhesions than the left.

At a session on January 5th, the Obstetrical Society discussed the *obstruction of labor by ovarian tumors in the pelvis*. SPENCER thought that if possible such growths should be pushed up out of the pelvis before the beginning of labor. Version, forceps, craniotomy, and incision or tapping of the tumor, should be rejected on account of their danger, and the abdominal operation is preferable to the vaginal for the removal of these tumors.

HERMAN said that a procedure described by Fritsch deserves fuller consideration. This consists in making an incision into the tumor through the vagina, and then stitching the margins of the opening together so that the cyst contents may escape extraperitoneally. In this manner the danger of tapping is avoided.

PLAYFAIR said that he had been able to collect 183 cases, which show that this complication of labor is not so extremely rare. While admitting that ovariotomy is the best course to pursue, this, of course, depends somewhat on the experience of the surgeon, and also upon suitable nursing. If these conditions cannot be fulfilled, and it is impossible to push the tumor up out of the way, vaginal

puncture should be performed. The mortality in cases in which puncture has been performed is only eighteen per cent.

SOCIETY PROCEEDINGS.

KINGS COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held January 11, 1898.

THE President, J. C. BIERWIRTH, M.D., in the Chair.

DR. L. GRANT BALDWIN read a paper on

THE EARLY DIAGNOSIS OF MALIGNANT UTERINE DISEASE. (See page 300.)

DISCUSSION.

DR. HENRY C. COE: I felt very much complimented to be invited here this evening, and it occurred to me as I was crossing the bridge that the circumstances under which I came were quite different from those which have attended my former visits, and that I was no longer coming to another city, but simply to another part of the same great metropolis. This municipal union implies that the relations which will exist between us and our professional brethren in Brooklyn in the future will be even more friendly and intimate than they have been in the past.

The subject which the Doctor has so ably introduced is one of peculiar interest to me; in fact, I have been interested in it from the very first time I ever had anything to do with malignant disease. Every year the importance of the subject is more deeply impressed upon me. When we consider the fact that even the best German operators acknowledge that only twenty-five per cent. of the cases which come under their observation are in a condition for radical operation, and that gynecologists of wide experience in this country have made the statement that perhaps only ten or fifteen per cent. of such cases were operable when referred to them, it occurs to us that there must be something wrong—that there must be some reason why surgeons are not able to see a larger number of patients while the disease is still in the operable stage. Of course, as the Doctor said in his paper, a good deal depends upon the imperfect education of the laity in regard to the initial symptoms of malignant disease. Women are exceedingly loath to consult a physician, especially unmarried women who have passed the menopause and have never had any previous pelvic disease. They delay visiting their family physician even when they have marked hemorrhages. Many cases have come under my observation in which it was clear from the history that cancer had developed and that the symptoms had been concealed or disregarded for months until the time for successful interference had long since passed. As the author rightly said, the education of the laity is the first step in increasing the number of operable cases.

I am impressed with the great sameness in the history of cases of chronic carcinoma. Few of the unfortunates report their initial symptoms to their physician, or if they do, the doctor is easily persuaded that such are the ordinary phenomena of the menopause; and the disease is allowed to go on from month to month, and even from year to year, until finally an examination is made and it is found to be too late to do anything. It seems to me that the surgeon cannot be expected to accept all the responsibility in these cases. Of course he is not obliged to operate, but these patients are brought to him sometimes in the most advanced stage, with the expectation, or firm belief, that he is going to do a radical operation, and, contrary to his better judgment, he is led to attempt such an operation when he ought to let the patient alone. The contraindications to hysterectomy are becoming more strictly defined every year. I recently read an article by Olshausen in which he said that he would not attempt a radical operation in a case in which the disease was not absolutely confined to the uterus; but we rarely see cases in this stage.

Cases of carcinoma of the uterus are naturally divided into two distinct classes: those in which the disease involves the cervix, and those in which it develops in the body of the organ, and clinically there is a great difference between the two. I believe that patients with carcinoma of the body of the uterus are much more apt to reach the surgeon early than are those in whom the disease affects the cervix, because the former nearly always develops *after* the menopause, the hemorrhage is more significant, and the patient applies earlier for aid. The diagnosis is all-important, and we must rely to a certain extent on the microscope, but in this we are often disappointed. For example, in a patient with a typical hemorrhage, a portion of brain-like material removed with the curette is reported by the pathologist to be non-malignant, and yet we feel from the history of the case and from the condition of the patient that a radical operation is indicated. Under these circumstances the surgeon is naturally placed in a very disagreeable position. He is expected to give a positive opinion, and having once advised a radical operation, he must abide by his decision. I have more than once, after removing a uterus under such circumstances, opened it and felt immensely relieved to find my diagnosis confirmed; I am free to add that it has not always been confirmed. On one or two occasions I have been mistaken, not finding malignant disease at all; but I have often thought that if I were placed in a similar position in regard to a member of my own family, if the symptoms pointed to probable malignant disease of the body of the uterus, and there was a painful doubt whether such disease was present or not, I would prefer to have the patient undergo the risk of a radical operation rather than to remain in uncertainty for months, and possibly when the operation was done to find it was performed too late. I assume, of course, that all the ordinary means of settling the diagnosis have been exhausted. Apropos of menorrhagia as an initial symptom of carcinoma of the cervix in young women, to which reference has been made, I would emphasize the importance of this symptom following the normal puerpery. I have in several cases seen the disease advance rapidly in puerperal women. It doubtless developed during pregnancy, but gave rise to no symptoms, but soon after labor there were hemorrhages which were ascribed to an increase in the lochial flow. When the periods returned

they were unusually profuse, and an examination showed that the disease had made rapid progress, although the labor had been normal. So, we must always remember that during and after the puerperal month a profuse flow is always an indication for examination.

The reader of the paper has properly laid stress upon the fact that pain, cachexia, and foul discharge are the symptoms, not of incipient, but of inoperable, malignant disease. This is a most important point. If we wait until these symptoms appear, in the majority of cases we have waited until any operation is of little value.

Nowadays, the only test of the success of an operation for malignant disease is freedom from recurrence. We have passed the stage when mere recovery from the operation is considered success in surgery. This was the case a few years ago, but now a recurrence within a year is a reproach to the surgeon, and shows that either his diagnosis was not exact, or that his technic was imperfect. The day is coming when operations for malignant disease will be judged entirely by this test, and you will see that this will tend to limit hysterectomy for cancer of the uterus to a comparatively small class of cases.

It is often difficult to distinguish an old case of laceration of the cervix with marked erosion from one of epithelioma; indeed, the microscope shows that many of the former are just on the border line between benign and malignant disease. In these cases I always amputate the cervix, because I believe it is a prophylactic measure, and that by a thorough operation at this stage we may prevent serious trouble at a later date. In such a case I do not excise a piece of tissue for examination. Here, it seems to me, is a valuable application of the operation devised by our esteemed fellow-townsman, Dr. Byrne. It is gratifying to think that Dr. Byrne in his old age has succeeded in establishing his just claims after so many years of successful work. Some of the most successful operators are seriously considering the propriety of abandoning hysterectomy for carcinoma of the cervix except in the incipient stage, and these are just the cases in which the best results are obtained by the use of the galvanocautery. So here is a valuable application of this method—in case of doubt, amputate with the galvanocautery.

I recently called attention to the great difficulty of making a pathologic diagnosis in many of these cases, and also to the fact that we are sometimes a little hard on the pathologist. We scrape out a little tissue the size of a pin-head and expect him to tell us exactly what the condition is. When we submit a specimen to the pathologist we should send a complete history of the case, not telling him what diagnosis we wish to have established, but at least giving him some clew as to the suspicion which we entertain, and then let him confirm or disprove our diagnosis, as his subsequent studies may determine. But we should remember that we cannot entirely depend upon his report. I was assisting a prominent gynecologist not long since in an operation for removal of the uterus in a doubtful case, which fortunately turned out to be malignant adenoma. The pathologist's opinion was rather amusing. The patient was about sixty-five years old, but the pathologist reported that a fragment of tissue expelled from the uterus contained chorionic villi! A thorough examination of a suspected case cannot be made in one's office. I doubt if any one is capable of giving a trustworthy opinion (especially with regard to the advisability of a radical operation) without making such an examination under anesthesia. This applies particularly to a case of possible disease of the corpus uteri. Dilate the canal, explore the uterine cavity, remove a fragment with the curette for examination, determine the mobility of the uterus and the presence or absence of metastatic deposits—in fact, omit no means of determining the true condition. To see a patient in one's office, to hastily diagnose the case and appoint a day for a radical operation—such a practice will sooner or later lead to serious error, if not to loss of reputation. I could cite a number of instances in which some curious mistakes have been made. I saw a uterus removed when the supposed carcinoma was simply a piece of sponge which had been in the vagina for several months. I have, as a pathologist, examined several specimens in which there was no trace of carcinoma, and have seen uteri removed for a sloughing fibroid and for various conditions not malignant disease. These mistakes would seldom be made if the patients were thoroughly examined more than once before operation. The diagnosis is so difficult and so important that we ought to exhaust every possible means before we arrive at a positive conclusion.

DR. LEIGHTON: Mr. President, my own personal experience has been that the family physician is not consulted until the case has progressed to a stage at which operation cannot be considered. Such patients are very apt to keep their symptoms to themselves, or possibly ask a neighbor or a woman friend about them. There seems to be the same disposition, I think, in regard to cancer of the breast. For some unknown reason patients are often disposed to keep the knowledge of its existence from the family physician as well as from the surgeon.

THE PRESIDENT: I would like to ask Dr. Baldwin if there is, in the early appearance of epithelioma of the cervix, anything characteristic which enables us to distinguish clinically a case of early epithelioma of the cervix from one of benign granulation; and, also, if these benign cases, of which I have seen a great many, have any special tendency to become malignant.

There can be no doubt in my mind as to the very grave importance of the subject as Dr. Baldwin has presented it. The cure of a case of carcinoma of the uterus, in my very limited experience, depends entirely upon early diagnosis. I think the paper is extremely timely and important as calling attention to the difficulties of diagnosis and the errors which are continually committed by both the physician and the people themselves regarding cases of cancer of the uterus, and especially in reference to the early diagnosis of this dread affection.

DR. BALDWIN: There may be a different odor to a sloughing malignant tissue than there is to sloughing fibroid tissue; I have never been able to determine the difference, and I fail to see why there should be any. An odor is not present in malignant disease until sloughing occurs, and the same is true of a fibroid growth, and I doubt if in either

there would be an odor very different from that of decomposing steak under the same conditions.

As to the eroded cervix—whether cancer is a sequel of benign disease of this part of the uterus: In Dr. Emmett's statistics of malignant disease of the cervix, in the vast majority of cases there had been lacerations of the cervix, and I presume more or less erosion as well, and this has also been the experience of Dr. Byrne. In almost all cases the patients have borne children. Few of Dr. Byrne's cases were in single women, but the vast majority were in those who had borne children and sustained lacerations of the cervix.

I can hardly agree with Dr. Leighton that cancer of the breast is as late in coming under the care of the surgeon as cancer of the uterus. In my experience, a woman with a lump in her breast is very likely to seek advice; she worries about it, and while it is true that many conceal the affection, still I think in the greater proportion of cases cancer of the breast receives attention earlier than cancer of the uterus.

I think there is nothing in the granulations of an eroded cervix that is significant, but, of course, in some the appearance is that of malignant disease, and these are just the cases in which amputation of the cervix should be performed, as Dr. Coe has suggested.

REVIEWS.

MANHATTAN EYE AND EAR HOSPITAL REPORTS. Vol. iv. New York: The Knickerbocker Press, 1897.

THIS, the fourth number of the annual reports, is especially noticeable for the excellent articles on otologic and rhinologic subjects. Among them the papers on "Hysteric Deafness," by Dr. F. Pierce Hoover, "Disease of the Internal Ear," by Dr. T. J. Harris, and "Deflection of the Septum," deserve particular attention. Among the papers of ophthalmologic importance we notice "Asthenopia as a Forerunner of Neurasthenia," by Dr. D. B. St. John Roosa, and "Myopia Following Iridectomy," by Edgar T. Thompson, M.D. The volume concludes with a summary of cases treated and operations performed during the year.

ESSENTIALS OF BACTERIOLOGY. Being a Concise and Systematic Introduction to the Study of Micro-organisms for the Use of Students and Practitioners. By M. V. BALL, M.D., Bacteriologist to St. Agnes' Hospital, Philadelphia. Third edition, revised. Philadelphia: W. B. Saunders, 1897.

THIS little book, one of Saunders' Question Compends, is a very valuable one of its kind. The subject-matter is necessarily condensed, but the general arrangement of the material, the clear and concise modes of expression, and the rejection of all useless details, have produced a book which embraces most of the essential facts relating to bacteriology and laboratory technic.

In remarkably few words the author covers the ground of the classification, growth, methods of examination, staining, methods of culture, and appearances of bacteria. The commoner forms of non-pathogenic and pathogenic bacteria are then briefly described, and in an appendix the yeasts and molds, together with hints for the examination of air and water, receive consideration. The illustrations are ample, and for the most part, good; but the proofreading has not been careful.

In this book physicians and students will find an excellent means of acquainting themselves in a short time with the subject of bacteriology.

THERAPEUTIC HINTS.

Validol is a new remedy recommended by SCHWERENSKI in epilepsy and hysteria. It is a chemic combination of tincture of valerian and menthol containing an excess of the latter. The amount of menthol incorporated should be thirty per cent. The dose of the compound is from 10 to 15 drops, administered on sugar or in sweet wine. It excites gastric secretion, prevents fermentation and meteorism, while retaining full analgesic and antihysteric powers.

For Tapeworm.—LASS calls attention to the black oxid of copper as a non-toxic and efficient teniafuge. During the treatment acid foods and drinks should be avoided. For adults the remedy may be administered as follows:

℞	Cupri oxid.	ʒ iss
	Cretæ præp.	ʒ ss
	Boli albæ	ʒ iii
	Glycerini	ʒ iiss.

M. Ft. pil. No. CXX. Sig. Two pills four times daily during the first week, and three pills four times daily during the second week, at the end of which a dose of castor oil should be given.

For children the following is recommended:

℞	Cupri oxid.	gr. lxxx
	Cretæ præp. } aa Magnes. carb. }	gr. xv
	Tragacanthæ	ʒ iiss
	Glycerini	*m.* lxxx
	Sacchari	ʒ x
	Aquæ	q. s.

M. Ft. past. No. L. Sig. Two to three pastilles daily.

A Palatable Emulsion of Castor Oil.—

℞	Pulv. acaciæ	ʒ iv
	Ol. ricini	℥ i
	Elix. saccharini	*m.* xx
	Ol. amygdalæ amaræ	*m.* i
	Ol. caryophylli	*m.* ii
	Aq. dest. q. s. ad.	℥ ii.

M. Dissolve the gum in sufficient water, add the oil gradually, and finally the flavoring agents.

For Malignant Pustule.—It is recommended to inject subcutaneously from ten to twenty minims of the following solution, and to cover the affected area with sublimate compresses:

℞	Hydrarg. bicyanid	1 part
	Aq. dest.	100 parts
	Cocain salicyl.	q. s.

M. Sig. For hypodermic use.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXII. NEW YORK, SATURDAY, MARCH 12, 1898. NO. 11.

ORIGINAL ARTICLES.

SOME INSTRUCTIVE CASES OF APPENDICITIS.[1]

BY H. A. HARE, M.D.,
OF PHILADELPHIA;
PROFESSOR OF THERAPEUTICS IN THE JEFFERSON MEDICAL COLLEGE; PHYSICIAN TO THE JEFFERSON HOSPITAL.

IN this brief paper I desire to call attention to several cases of appendicitis which, it seems to me, possess more than ordinary interest:

CASE I.—Male, nineteen years of age, came under my care for a sharp attack of pain in the abdomen, which was not referred to the region of the appendix, but was said to be half way between the ensiform cartilage and the navel. The patient presented the history of no less than nine such attacks during the previous six months, some of them so severe that the hypodermic use of morphin was necessary. In none of them was the pain appendicular in character. As soon as the abdomen was exposed it was seen that there was a swelling of considerable size in the right inguinal region. On palpation this swelling proved to be only slightly tender, but very hard and resisting. Even when the somewhat rigid abdominal wall over it was relaxed the mass remained hard and brawny under my fingers, and was so large, and dipped down so deeply, that its extent could not be accurately determined. The possibility of malignant growth seemed to be excluded by the age of the patient, the unimpaired general vitality, and the history of the attacks, which were usually associated with some nausea and vomiting, and the general typical symptoms of appendicitis. The diagnosis was recurrent appendicitis with great thickening and deposit of inflammatory exudate about the appendix, and perhaps about the entire caput coli.

In other words, the patient had had acute appendicitis several times, with surrounding exudation and a chronic inflammatory process between the attacks. The large mass of exudate made it evident that an operation during the acute process would not only be difficult but possibly fatal as well, and, therefore, nothing was said to the patient about operative interference. After recovery from the last attack the patient refused operation, but after being impressed with the fact that nine attacks within six months indicated the speedy development of others, and that in any one of these a fatal result might ensue, and, on the concurrent advice of one of our most able surgeons, he at last gave a reluctant consent to the operation.

He was operated upon during the period of quiescence, and the appendix was found greatly enlarged, thickened, and surrounded by a mass of exudate. It was removed with some difficulty, but with no serious damage to surrounding tissues. The operation was well borne, but within twenty-four hours nausea, followed by stercoraceous vomiting, ensued, and the patient speedily died. There were no other signs of obstruction, and collapse came on so quickly that nothing could be done for his relief. I still think my advice was theoretically good, but practically the man would have lived longer if he had not consented to the operation.

CASE II.—This case is in some respects the opposite of the one just reported. A man aged fifty-five years, had had at intervals of six months two attacks of violent abdominal pain and all the other symptoms of acute appendicitis. The last attack occurred two months before I saw him, when he came from a Western city for advice as to operation. At my request he was examined, in consultation, by two surgeons of high repute, who found some tenderness but no marked induration. As he was forced by his employment to be constantly traveling through small towns he feared an attack when away from home and competent skill, and, while naturally not desirous of operation, was willing to have it performed if it was thought that recurrences were probable. One surgeon advised operation as a prophylactic and curative measure, the other and myself agreed that it would not be necessary. This was four years ago, and there has been no sign of a third attack, the patient being at present perfectly well.

CASE III.—A man, aged thirty-eight years, who, six months before I saw him, began to have severe pain in the right inguinal region. Usually he had a paroxysm of pain about every week, and sometimes more frequently. The pain was sharply localized, and at McBurney's point there was great sensitiveness, although when the examination was made there had been no attack of pain for a week. The patient had lost ten pounds in weight since the attacks began, but his appetite was good, although he was constipated. He was treated by absolute rest, a careful diet, and regulation of the bowels. He did not have an attack during nine days previous to leaving my care. The tenderness disappeared, as did the patient, so the subsequent history cannot be reported, but in the light of the first and second cases I am glad I did not urge operation. An interesting point in this case was an entire absence of fever during the attack which the patient had while under my care.

CASE IV.—A woman, aged forty-eight years, was seized in the middle of the night with agonizing abdominal pain situated in the epigastric and left inguinal regions, or between the latter and the median line. I

[1] Read at a meeting of the Philadelphia County Medical Society, March 9, 1898.

saw her eight hours after the pain began, and found her still suffering greatly, but without agony. She had all the classic symptoms of appendicitis: vomiting, pain, and exquisite tenderness over the appendix. The pain was so diffused that it was hard to tell exactly where it was most severe. The abdomen was scaphoid-shaped and somewhat rigid. The appendicitis was so acute that I did not dare to advise against an operation, and the weather so hot and the patient so feeble that I much feared the results of surgical interference. A well-known surgeon suggested operation, and then, as I did not like to oppose my views to his, I called in a medical consultant who agreed that while an operation was strongly indicated by the local condition, the hot weather and feebleness of the patient were greater dangers than the affection itself, especially when added to the effects of operative interference. Operation was not performed, the patient received local and general treatment and recovered in about three weeks. This occurred during June, 1895. Since then there has been no return of the trouble, and for a third time I am glad the knife was not used.

Case V.—A woman, aged thirty-three years, who, between January 1st and May 15th, had four attacks of appendicitis, each of greater severity than its predecessor. An operation during each attack had been refused, and also between the attacks. When the attack in May occurred, the case was so evidently an operative one that operation was insisted upon and was at once performed.

The operation revealed an abscess at the tip of the appendix, containing about one dram of pus. The abscess was ruptured during removal of the appendix. The wound was, however, carefully cleansed and all pus apparently removed. The patient then progressed favorably for two weeks. The wound healed by first intention and all seemed well, though there was no gain in strength. At this time the temperature gradually began to rise and to be more and more marked, so that the chart resembled that of intermittent malarial infection. The old wound showed no sign of infection, the blood no evidence of malaria, and there was no history of malaria. The wound was then opened, found healthy, and again closed. There was still fever and persistent loss of weight. Finally, the wound was opened a second time, on this occasion down to the site of the appendix, and still everything was apparently normal. The fever persisted, though sweats and chills were absent. Six weeks after the operation, the patient was seized with severe pain in the abdomen, the temperature suddenly became accentuated, and she became partially collapsed. An examination of the abdomen now revealed for the first time a marked swelling in the right inguinal region as well as pronounced evidences of peritonitis. An operation was advised as the only resource, but after the belly was incised the patient so nearly died on the table that it had to be given up. Death occurred two days later, and at the post-mortem a large abscess of the right ovary and tube was found from which general peritonitis had resulted. Infection of these parts had evidently occurred from the ruptured appendix, as the woman was unmarried and a virgin. The delay of operation in this case till the abscess was ready to rupture on the slightest touch, ultimately caused the death of the patient.

Case VI.—Male, aged forty years, very stout, and of large frame. The patient was seized in the night with excruciating pain in the groin and throughout the whole abdomen. When seen by me, six hours later, the abdomen was already swollen and rigid. The pulse was rapid, but otherwise good. The abdomen was exquisitely tender. Operation was insisted upon, and was performed within an hour. The appendix was found gangrenous at its tip. He promptly recovered, and the operative interference without doubt saved his life.

Case VII.—December 26, 1896, I was called to see R. L., male, aged ten years. I found him suffering from a moderate degree of pain which was situated in the right iliac region. He was in bed, had a coated tongue, and a temperature of 101.5° F. The history was that he had been taken during the night with several paroxysms of fairly severe pain, and had had several that morning. A week before, upon going to bed, he had had some nausea and gastric disturbance, probably due to intemperance in diet. Close questioning revealed the fact that during that week he had also had considerable pain in the bowels, although by no means so severe as at the time he was first seen by me. Not only was there marked tenderness over McBurney's point, but as I have frequently noticed in such cases, the patient complained of a good deal of pain in the neighborhood of the transverse colon. Placing a hand under the flank, or in other words, behind the appendix, seemed to reach the most tender spot. That evening I asked his relative, Dr. Howard A. Kelly, to see him in consultation, and it was decided that the best thing to do was to insist upon perfect rest, a liquid diet, and no medicine.

On the following day the pain was about the same, as was also the rigidity of the abdominal walls. As he had been freely purged on the 25th by means of citrate of magnesia and cascara sagrada it was thought wise not to administer any purgatives at this time. On the morning of the 28th the swelling and tenderness in the right iliac region was increased, and the pain was stated by the child to be much more severe. Another consultation with Dr. Kelly was requested, and he decided that it would be advisable to freely administer Rochelle salts. This was done, but after the third dose of a teaspoonful, vomiting occurred. Castor oil was then substituted, and two hours later resulted in two free movements of the bowels. The temperature during the 27th and 28th was about 99° F., both morning and evening. On the morning of the 29th, the pain seemed to be slightly relieved for a time, but the tenderness on palpation was quite as marked as ever, and the boy stated that the pain was returning as the hours passed by.

It was determined that it would be wise to interfere surgically, and an operation was performed on

that day (Tuesday) by Dr. Kelly, assisted by Dr. C. P. Noble and two of Dr. Kelly's assistants from Baltimore. The appendix was found markedly inflamed, but it did not contain pus. There was a slight peritoneal hyperemia all around the neighborhood of the appendix. The boy did very well after the operation; his temperature did not rise above 99.5° F.; vomiting was very slight, and the case progressed favorably for a period of ten days. On Monday, January 10th, the patient was seized, however, with violent pain in the abdomen. On examination the abdomen was found to be neither scaphoid-shaped nor swollen, although it was tympanitic on percussion. Pain was excessively severe, and seemed to have its greatest point of intensity in a line drawn between the nipple and the anterior superior spine of the ilium to the right of the umbilicus. At this point it was thought, on careful examination, that there was increased resistance. The pain continued during twenty-four hours, notwithstanding the administration of $\frac{1}{16}$-grain of morphin, which gave relief only for a short time. The temperature remained about normal.

The next day, however, retching and vomiting became prominent symptoms, and, although not constant, occurred with sufficient frequency to be considered a grave indication. He had been unable to pass anything from the bowels from the time the attack began, though no food had been given him which could in any way have produced intestinal complications. Repeated rectal injections failed to have any result, except on one occasion, when a slight quantity of gas was passed. In view of his grave condition it was decided, two days later (Tuesday the 12th), that something must be done for his relief, and, after consultation between Dr. Edward Martin, Dr. Kelly, and myself, it was decided that the boy should be etherized, inverted, and that copious intestinal irrigation should be resorted to. At this time the boy was vomiting small quantities of liquid of a coffee-ground or grumous appearance, mixed with streaks of bright-colored blood, and there was marked abdominal distention. One and a half quarts of warm saline solution having been injected into the bowel without reducing the obstruction, the boy was placed upon the operating-table. After the injected liquid had been drained out by means of a rectal tube, Dr. Kelly opened the abdomen half-way between the umbilicus and his earlier incision for appendicitis. A small quantity of liquid was found in the abdominal cavity, there was evidence of slight peritonitis, and two large knuckles of gut were found adherent to the abdominal wall, producing intestinal obstruction by preventing peristaltic movement. The bands of adhesions were broken up, the wound was closed, and the child put back to bed in fairly good condition considering the gravity of the case. Twenty-four hours after the operation the bowels moved freely, and a considerable quantity of fecal matter was passed.

The patient made a good recovery from the operation, and was kept on a strict liquid diet for a period of four or five days. His temperature during this period never being febrile, but he suffered from time to time from more or less violent attacks of abdominal pain. His condition, however, steadily improved until Tuesday, February 2d, when I called at 4.30 A.M., because he was suffering from violent pain which was not relieved by a hypodermic of morphia given at 6 P.M. the previous evening. I found him with excruciating abdominal pain, a tense and rigid abdomen, and some slight nausea. The boy had not had a movement since the previous morning. Morphin ($\frac{1}{10}$-grain) was given hypodermically, and though repeated at 9 A.M. the next morning, did not afford material relief. I immediately telegraphed for Dr. Kelly, and, after a careful examination, it was decided that he had about one and a half quarts of liquid in his abdominal cavity, and that there were evidences of adhesions obstructing the intestines. In view of the gravity of a third operation it was decided by Dr. Kelly, Dr. Martin, and myself to take the risk of waiting twenty-four hours. At the end of that time, the various rectal injections having failed, another one was given with the result that he passed a large amount of fecal matter, following which the pain subsided. Convalescence was established, and the boy was considered cured, Friday, February 19th, although at that time there was still present, as there had been from his first getting up, February 10th, slight impairment of power in the lower extremities (partial paraplegia).

These cases, which are taken as types from a larger series, illustrate the fact that the physician assumes a grave responsibility if he urges an operation, perhaps as grave as if he opposes it; that he cannot afford to leave a decision as to the wisdom of operation entirely to his surgical colleague, and, finally, that patients with appendicitis often recover and remain well, or, in other words, in all cases an operation is not necessary, either for immediate relief or for the prevention of other attacks. On the other hand, there are cases which are so fulminating in character that an hour's delay is dangerous, and I am inclined to believe that in cases with early fixation of the body and abdominal muscles and without much temperature disturbance, operation is more necessary than in those in which the pain is greater, more continuous, and more severe on pressure.

COMPOUND FRACTURES INVOLVING THE ANKLE-JOINT.

BY C. C. WORDEN, M.D.,
OF NASHVILLE, TENN.

IN the consideration of this subject the ordinary classification of injuries to the ankle-joint will be adopted; for the reason that any simple fracture may become compound in a proportion varying directly with the quality of the injuring force. It is impossible, however, to determine exactly which bones are invariably involved in such injuries, or the man-

ner in which they are broken, since there may be a fracture of any or all of the three bones forming the joint, the lines of fracture varying with the quality, quantity, and direction of the violence producing the injury. In addition, it will be necessary to include in the classification such bones as serve to maintain the integrity of the joint, though not directly contributing to its formation. The subject, then, must embrace such compound fractures as involve the tibia, fibula, whether malleolar or supramalleolar, astragalus, and the os calcis, when the latter shares the injury with the foregoing. Fractures of the tibia or fibula, alone or together, above the malleoli, as a general rule do not involve the joint, even when they are compound. The exceptions are noticed in cases in which the lacerations are prolonged into the joint, either from severe lacerating or continued force, which, after causing the fracture, continues to act. As an example of such force may be mentioned an injury to the ankle from being caught between two objects, the one stationary and the other in motion.

Injuries Caused by Eversions of the Foot.—A classic Pott's fracture when compound will usually show the laceration high above the malleolus and opposite the site of the break in the fibula; but cases are frequently observed in which the laceration occurs opposite the internal malleolus. In such an instance the eversion of the foot is extreme and the fractured inner malleolus generally presents in the wound. In these injuries the unyielding internal lateral ligament carries downward the tip of the malleolus, the synovial sac is opened and the joint exposed. The obliteration of the mortise permits an inward dislocation of the astragalus which follows the outward displacement of the foot. The same force may cause a fracture of the outer articular border of the tibia, or a laceration of the tibiofibular, or interosseous ligament, and a consequent dislocation of the tibia inward. In these instances we may expect to find a laceration of the anterior fasciculus of the external lateral ligament, the reason for this being that the astragalus partakes of the outward deviation of the foot and swings inward while the lower fragment of the fibula is carried outward. This allows partial luxation of the astragalus inward. The degree of the luxation depends upon the severity of the injury.

Fracture of the inner malleolus alone, when compound, may or may not be accompanied by dislocation of neighboring bones. The chances are that partial dislocation will occur if the fracturing force be violent, for the reason that the line of fracture through the malleolus is usually transverse, or nearly so, and sufficiently high up to destroy the inner side of the mortise and allow the joint-fluid to escape. When the external lateral ligament yields the degree of luxation may be extreme, the superior articular surface presenting inward. This is facilitated by a fracture through the lesser process of the os calcis.

As a result of forcible eversion of the foot the external malleolus may be fractured and compounded at the site of the fracture, below and posterior to it, or near the internal malleolus. It will usually be found in such cases that the foot has not only been everted but carried bodily outward as well. The astragalus glides outward from its socket with little or no obstruction, and is largely instrumental in causing the compounding of the fracture. A fracture of the lesser process of the os calcis may complicate such extensive injuries, and it is usually accompanied by marked deformity. In the study of injuries of this nature there must be borne in mind the liability of involvement of the blood-vessels, nerves, tendons, and soft parts generally.

Fractures Caused by Inversion of the Foot. — Compound injuries resulting from this cause are more common than elsewhere about the joint because of the more exposed position of the fibular surface and the greater frequency with which the foot encounters inward displacement. Since any fracture of the ankle may by chance become compound it will be well to consider such injuries as commonly occur in this region. The arrangement of the fibers of the external lateral ligament predisposes to two varieties of injury. Either there will be a transverse fracture of the outer malleolus at the tip or base, more commonly the latter, or a fracture of the sustentaculum tali, or of both. By reason of direct pressure of the astragalus upon the inner malleolus the latter is often broken. The forcible eversion of the astragalus brings pressure to bear upon the deltoid ligament, the inner malleolus, and the lesser process of the calcaneum. If this powerful ligament refuses to yield the result will be a vertical line of fracture through the lesser process unless the inner malleolus yields first. The astragalus itself may be broken, particularly when the breaking force is vertically and laterally applied. The line may run transversely and include merely the tibiofibular articular surfaces, or may run vertically and from before backward anterior to the tibial articular facet. When the injury is severe the following may be presented: The laceration on the outer aspect of the ankle widely gaps, revealing the tibial articular facet of the astragalus which lies upon its side. The foot may be straight or strongly inverted, depending upon the amount of damage to the calcaneum and the calcaneo-astragaloid ligament. The tibia may show a

line of fracture running transversely less than a centimeter above its articular surface, and in this respect differing from a supracondyloid fracture. The fibula usually breaks at a point about an inch lower than in Pott's fracture, and shows a transverse line of fracture or even multiple lines.

Fractures Due to Crushing Injuries. — Under this division may be classed such severe compound fractures as result from severe crushes and falls upon the feet. The damage to the joint and soft parts is extensive and usually amounts to disintegration of the former. The articular surfaces of the tibia, fibula, calcaneum, and astragalus are commonly ground in pieces, the periosteum badly torn, and the soft parts pulpified. It would be useless to attempt any classification of such injuries. The amount and variety of damage is, of course, variable.

The *symptoms* of compound fracture involving the ankle-joint are those of simple fracture, modified, however, by the damage to the soft parts.

The *diagnosis* depends upon the symptoms and physical signs, and is facilitated in a ratio variable with the extent of the compounding.

In the *treatment* of such injuries the surgeon has no set rules to follow. Each injury is a law unto itself. Each patient rightly may demand two-fold efforts: those directed toward maintenance of the best general condition, and those which aim to preserve the joint. The former may demand the abandonment of the latter. In general the treatment may be said to consist of reduction of the fractures or dislocations and in cleansing the joint and closing the wound under strictest aseptic rules, and lastly, immobilization of the affected part by some suitable devise. When reduction is easily accomplished and there is little tendency to subsequent displacement, any unnecessary manipulations or interference with the wound should be rigidly interdicted. The exception are those cases in which the joint is full of macroscopic particles of dirt, filth, pieces of stocking, etc. It is wise to let the joint alone when evidences of contamination are wanting.

In cases in which the deformity is not easily corrected and in which it is difficult to maintain the fragments in position, as, for instance, when the astragalus has turned upon its side, it is perfectly allowable to manipulate the parts through the laceration. When the wound is merely a puncture it is better to further incise and carefully inspect the field of injury. By so doing the deformity is better corrected and the prognosis is not altered. In this connection there appears a class of cases that demands a similar procedure: When the injury has caused an irreducible deformity and extensive mangling of the soft parts, without actual compounding, the joint and tissues will be found full of blood. It will become evident that on account of the damage the pressure from within will not allow the skin to recover its vitality and thus will cause it to slough. By rendering the injury compound the deformity may be remedied and the hemorrhage checked. Failure to properly reduce recent deformity will call for subsequent consideration of various operative measures, including actual resection of the joint. When the articular surfaces about the joint are badly shattered, resection at the time of injury, or later, will yield good results; under such circumstances ankylosis is, of course, expected.

As to the question of amputation: It is always better to preserve the foot, if possible, unless by so doing the patient's chances of recovery are lessened. If the patient be in good general health, and the circulation beyond the site of injury can be maintained, it is best to try and save the foot. A plaster dressing to the leg and foot, with fenestræ or interruptions where necessary, and suspension of the limb will meet the requirements in the vast majority of cases. Anterior and posterior splints of iron embedded in the plaster and arched over the fenestræ or interruptions will afford better support and greater rigidity to the part.

Case I. — F. S., Swede, forty-five years of age, an iron miner, of large and powerful frame, and in rugged health. July 12, 1897, while he was riding on an ore-dump the car jumped the track and jammed his ankle between the axle and a pile of rails lying by the tramway. The man was brought to the hospital and anesthetized. Examination showed the following condition: On the outer aspect of the leg and foot was an irregular laceration of the skin and soft parts, four inches in length, extending from a point one inch above the malleolus, across it, downward and forward. The external and anterior fibers of the external lateral ligament were torn across. The fibula was broken transversely immediately above the malleolus. The astragalus was luxated forward and outward sufficiently to show nearly all its superior articular surface. The interosseus ligament was intact. The malleolus was in relation to the astragalus, the anterior and posterior ligaments having yielded. The foot was decidedly inverted. The tibia and deltoid ligaments were not damaged. Hemorrhage was slight. The wound and joint were full of pieces of yarn, shreads of leather, and hematite. The foot, and the astragalus with it, were easily replaced in a normal position, and the outer malleolus carried into its proper relation. There was little or no tendency to subsequent displacement.

The laceration was closed with interrupted silkworm-gut sutures. The foot and leg, from toes to knee, were encased in plaster over a stout anterior splint of iron. In this dressing large fenestræ were left over the site of the wound. The wound was

antiseptically dressed. Three days later a few of the stitches below the malleolus and in the middle portion of the laceration were removed to facilitate the discharge of a small quantity of pus, the presence of which the thermometer had indicated. Subsequently the reopened wound healed by granulation. The upper and lower sutures held and secured primary union. At the end of six weeks the dressing was removed. The foot was in excellent position and the wound entirely closed. The motions of the joint were not less than would be expected from such a period of enforced rest. The patient walked without crutches on November 1st, and returned to work one month later. There was at that time no impairment of motion, nor was there the slightest limp. The only evidence of injury was the cicatrix of the laceration.

Case II.—L. O., Swede, thirty-eight years of age, and by occupation a carpenter. The patient had pulmonary tuberculosis. Bacilli in great numbers were first demonstrated to be present in the sputum during March, 1897. His wife was then in an advanced stage of the same disease. June 24, 1897, the patient was building a cellar-way at the hospital. He attempted to walk across the top of the opening on a board one-half inch in thickness. The plank gave way letting him fall a distance of eight feet, striking the outer half of the plantar surface of his right foot on the edge of the bottom step in such a way as to cause strong abduction. He was immediately carried into the hospital and anesthetized.

Examination showed the following injury: The foot was everted to an angle of eighty degrees with the shaft of the leg. The laceration was long and irregular, running downward and forward just beneath the internal malleolus. The tibia protruded about three inches and showed a transverse fracture one centimeter above the articular surface. The shaft was not injured. The astragalus was badly shattered, being broken vertically and transversely into several fragments. A vertical line of fracture traversed the lesser process of the calcaneum. The interosseus ligament and the external lateral ligament appeared to be intact. The fibula was comminuted. There was a transverse supramalleolar fracture, and also lines of fracture running through the malleolus forward and inward and forward and downward. Hemorrhage was not severe. In order to manipulate the fragments of the astragalus it was necessary to enlarge the laceration. None of the fragments seemed to be entirely detached. They were replaced with some difficulty. The foot was brought into proper relation to the leg and the articular surface of the astragalus, that is, what remained of it, placed in apposition with that of the tibia. The comminuted external malleolus was pressed and molded into a good position against the astragalus. The circulation in the foot was good, the anterior and posterior tibial arteries having escaped injury. A rubber drainage-tube was placed in the central portion of the laceration, and another was introduced through a counter-opening made just anterior and below the tip of the external malleolus. The laceration was then sutured above and below the tube. The foot and leg were encased in a plaster dressing over anterior and posterior iron splints, leaving an interruption at the ankle. The limb was suspended and swung clear of the bed. On the third day the tubes were removed. Considerable foul pus had found its way out of the wound. This discharge continued uninterruptedly. Some fragments of the astragalus necrosed, and a probe detected softening of almost the entire bone, and also of the articular surface of the tibia. By August 1st the counter-opening had closed, but the sloughing of the necrosed fragments continued through the original laceration. By the end of the month the discharge had greatly diminished. The sinus persisted and was about an inch in depth. The patient's general condition was not seriously impaired.

At the present time the patient is about on crutches, and he rests a fair amount of weight upon the foot. He complains of pain, but indicates it well forward in the tarsus, the usual situation of pain after long immobilization of the foot. The sinus persists, and is three-quarters of an inch in depth. The discharge is thin and scanty. There is a limited yet fair amount of motion. The patient's general health does not improve. Tubercle bacilli in great numbers are present in the sputum. It will be safe to assert that the patient will not survive sufficiently long to ever have the use of a sound though perhaps ankylosed joint. The accident occurred in the region of Lake Superior, where the summer is brief and the winters trying to persons of rugged health, and disastrous to those with tuberculous tendencies. It seems to me that it would have been better surgery in this particular case to have amputated the foot and spared the patient the tedious months of suppuration during which he was confined to his room. The chances for ultimate use of the foot are nil, and the shock following amputation would not in all probability have exceeded that of the original injury. Crutches were inevitable in any case, yet their earlier use, following amputation and the patient's increased out-door activity during the most favorable season of the year would have contributed much to his well-being. This is particularly true since he was in an early stage of consumption at the time of the accident.

Case III.—E. P., a Finn, of temperate habits, and in robust health, twenty-eight years of age. His occupation was gold-mining. November 23, 1897, his left ankle was caught under a "fall of ground." Examination should a long, jagged laceration through the skin and soft parts on the outer aspect of the left ankle. There was slight inward displacement and rotation of the foot. The articular surfaces of the tibia and fibula were crushed and pulverized. The astragalus and sustentaculum tali had met a similar fate. The wound and joint were ground full of dirt. The soft parts all about the ankle and well forward on the foot were badly crushed. Pulsation of either the anterior or posterior tibial artery could not be detected. Hemor-

rhage was free, but not severe. The patient rode five miles to the hospital in an open sleigh. As he was suffering from shock and cold he was immediately put to bed, warmth and stimulants exhibited, a temporary dressing applied to the injured limb, and every effort made to arouse the circulation in the foot. It soon became evident that the part was dead. Accordingly, on the following morning, an amputation was performed at the lower third of the leg. Had the integrity of the circulation been maintained there would have been an attempt to favor the man's condition by the following operative measures. The loose fragments of the tibia and fibula would have been removed and both bones sawed transversely through immediately above the uneven line of fracture. The astragalus would have also been removed, and the superior articular surface of the calcaneum sawed or chiseled off transversely. The tibia and fibula would have been wired together, the foot carried up, and the os calcis wired to both the tibia and fibula. Ankylosis would have been the object sought.

The man made an excellent recovery following the amputation, and at the present time goes about with the aid of an artificial limb.

MASTOIDITIS.

By WM. C. BANE, M.D.,
of Denver, Col.

Diagnosis.—Mastoiditis is seldom a primary affection, being usually a complication of otitis media. It is characterized by pain and tenderness in the mastoid, at first slight, but rapidly becoming both severe and persistent, especially at night, disturbing or preventing sleep. The pain may radiate to the temporal, occipital, or supra-orbital regions. Tenderness on pressure or on percussion of the mastoid, over the antrum, the tip, or both, will be complained of if the inflammation has continued for a few days. In exerting pressure it is necessary to avoid the auricle, in view of the fact that the pain excited in the inflamed canal or middle ear may be misleading. In some persons the tip of the mastoid is normally quite tender. Edema back of the ear may or may not be present, even though the interior of the mastoid be necrotic. However, there is usually more or less infiltration of the tissues over the mastoid in the acute and sub-acute forms of mastoiditis.

With periostitis, there is tenderness, redness, and swelling over the mastoid. Fluctuation is indicative of the presence of a subperiosteal abscess, in which case there is usually displacement of the auricle. Inflammation originating in the external canal may extend to the periosteal covering of the mastoid and finally result in the formation of an abscess. In young subjects it may pursue such a course from the middle ear without perforating the cortex, having found exit through the Rivinian segment.[1] In children, in whom the cortex is quite thin, perforation may occur within a day or two after the pneumatic cells have been invaded. The abscess occasionally ruptures through the internal surface of the mastoid, and thus pus enters the tissues beneath the sternocleidomastoid muscle. This was true of a case which I observed a few years ago. The local temperature, according to Politzer,[2] will frequently be elevated above that of the healthy mastoid. Body temperature is an uncertain guide. During the acute stage it may vary from normal to 103° F. When the more acute stage is over the temperature may be normal even though the destructive process still continues. When the temperature fluctuates, rising and falling suddenly several times within twenty-four hours, it is indicative of involvement of the lateral sinus. The pulse under such circumstances is rapid, small, and thready.[3]

Abscess of the mastoid complicating acute otitis media is usually located in the middle and lower portions of this bony process contiguous to the cortex. Politzer's observations have led him to believe that the mastoid abscess is isolated and almost without exception has no communication with the antrum.

In most cases of mastoiditis originating during the course of an otitis media it will be observed that the posterior-superior wall of the meatus, near the drum membrane, is bulging and tender. When the canal is thus depressed in a case of otitis media purulenta, and in which there is a history of pain and tenderness in the mastoid, and perhaps a variation in the local and general temperature, a diagnosis of mastoiditis is justifiable. The bulging of the posterior-superior wall of the canal, like the pain in the mastoid, is not always present. In January of the present year I operated in two cases of mastoiditis, in neither of which was there a bulging of posterior-superior wall, nor the typical pain of mastoiditis, and yet in both the mastoids were diseased. In one I exposed half an inch of the lateral sinus before all the necrotic tissue was removed.

Prognosis.—Mastoiditis is a grave malady, though when it complicates acute otitis media, if promptly treated, the prognosis is generally favorable. During the exanthemata, however, its progress is rapid and destructive, and efforts to check it are not usually successful. When mastoiditis develops during the course of chronic otitis media the outlook is grave, especially when there is a history of previous attacks of a subacute character. The inflam-

mation of the ear which so frequently develops during an attack of influenza is usually severe, and often extends to the mastoid.

When the discharge in otitis media and mastoiditis does not find free exit through a perforated membrane, the pus may find its way through the mastoid cortex, outwardly, anteriorally, or even into the digastric fossa. It may enter the middle fossa of the brain through the roof of the antrum or tympanic vault, or possibly the region of the lateral sinus.

In a few cases of mastoiditis recovery occurs without an operation, yet in order to prevent bone destruction and brain complications vigorous abortive treatment is necessary. Delay may result in brain abscess, sinus thrombosis, phlebitis, or meningitis.

On March 20th, of last year, I saw two cases of lepto-meningitis which had resulted from otitis media. In both, the disease had invaded the brain through the tympanic vault. One case was in a strong, muscular man, about middle age, whom I saw in consultation. He was in a semi-comatose condition. A history of long standing otorrhea was obtained. An operation was performed within a few hours, and revealed the existence of extensive caries of the mastoid and middle ear, with a perforation through the tympanic vault. The prognosis was, of course, very unfavorable, and the man died within twenty-four hours. At the post-mortem evidences of extensive meningitis were found.

The second case was in a robust young man, who several weeks before had had an attack of otitis media, which, under treatment, had subsided. Shortly after, and following exposure, there occurred a second and subacute attack of the same affection. This was followed by brain symptoms. The mastoid was opened by a colleague, but the operation did not result in finding any evidence of disease. Symptoms of meningitis developed. At the autopsy a purulent meningitis (limited to the posterior fossa) was found, the pyogenic material having entered the brain cavity through the vault of the tympanum.

Treatment.—When a case of mastoiditis comes under observation at an early stage abortive treatment should be tried. This consists of rest in bed, light diet, and free evacuation of the bowels obtained by the administration of calomel and a saline. If the drum membrane is congested and bulging it should be freely incised through its posterior-superior portion. The incision should also extend for a short distance along the posterior-superior wall of the canal to allow free drainage from the middle ear and attic, as well as depletion of the wall adjacent to the antrum. When a perforation exists it may be necessary to enlarge it in order to provide free drainage. The ear should be irrigated with a hot antiseptic solution several times daily. Cold, applied by means of the Leiter coil, or Bishop ice-bag, is a valuable aid in checking the inflammation, and should be continuously employed during twenty-four to forty-eight hours.

Dench[1] mentions a diagnostic point in the application of cold, in that if the pain is neuralgic, it will be increased by cold, but if due to inflammation, it will be diminished. Local blood-letting by means of either the Swedish or artificial leeches will render valuable service in plethoric subjects.

Following this treatment there may be an apparent improvement in the symptoms; but if, on reexamination, it is found that the tumefaction and tenderness still continue, surgical measures should be at once instituted. Dench states that "this experience has so often fallen to my lot that I never continue the effort to abort the attack for more than forty-eight hours, feeling certain, if marked improvement has not occurred in this time, that operative treatment will be subsequently necessary." The pain may be modified by the administration of codein and acetanilid; the latter, of course, also reduces the temperature. When general headache exists, the ice poultice, consisting of bran and pounded ice, will render valuable service. If abortive measures fail after two- or three-days' trial, longer delay is unwise, especially if the mastoiditis has developed during the course of a chronic otitis media.

In mastoiditis complicating acute otitis media it is safe to continue the treatment a longer time before instituting operative measures, as in such cases the abortive treatment often gives relief.

Operation.—When a subperiosteal abscess has formed it should be evacuated by an incision about three-eighths of an inch back of the auricle and parallel with it. Should there be a fistulous opening in the bone it will be necessary to proceed as in a regular mastoid operation. When an operation is to be performed, the head, for a distance of three inches from the auricle, should be shaved, and cleansed with soap and water, with ether, and then with a 1-to-1000 solution of bichlorid of mercury. At this day it is not necessary to emphasize the necessity of careful asepsis and antisepsis, the details of which may be safely left to the judgment of the operator. Before the operation the patient's bowels should be moved, and no food given during the previous six hours. The necessary instruments consist of scalpel, periosteum elevator, artery forceps, retractor (Allport's being one of the best), chisels, mallet, curettes, spoons, gouges, probes, scissors, and rongeur forceps. The head should be covered with sterilized towels, leaving exposed the region to be operated upon.

The exact method of procedure cannot be known

[1] Dench, "Diseases of the Ear," page 450.

in advance of the operation. The incision down to the bone should be made from the tip of the mastoid to a level with the upper attachment of the auricle, about three-eighths of an inch from the posterior attachment of the latter. The periosteum should then be elevated, and the retractor placed in position. If no fistulous opening is observed in the bone, an opening should be made with the chisel over the antrum. The opening should be made close to the posterior bony wall of the meatus, and not above its upper margin.

After entering the cortex, if the interior is found to be necrotic or soft, the narrow rongeur forceps can be used to remove this portion of the bone, after which the interior, or all unhealthy tissue, may be removed with a sharp spoon. If it is desirable to excise the posterior canal-wall, it can be very conveniently accomplished with the narrow rongeur forceps (Bacon's) and chisel. All the diseased tissue must be removed, even though in doing so it becomes necessary to expose the lateral sinus and facial nerve. Great care is necessary to avoid wounding the facial vein or nerve.

It is very important that the operator be familiar with the anatomy of the parts, as well as to know that in no two cases will the mastoid be found of the same shape, density, or thickness.

During the operation frequent drying of the wound with sterilized gauze is necessary, to permit observation of the depth of the wound and determination of the condition of the tissues. After removing all dead and diseased tissue the wound should be freely irrigated with salt or bichlorid solution. The upper part of the flesh-wound may be closed with stitches, down to the upper part of the cavity in the bone, after which it should be loosely packed with sterilized or iodoform gauze. Between the edges of the flesh-wound only a thin layer of gauze is required; thus the parts will earlier assume their normal position. Next, over the whole operative area, should be placed several layers of sterilized gauze, and then a layer of cotton, all of which is held in place by a gauze bandage.

It is not necessary to change the first dressing for four or five days, unless the wound becomes painful, or the temperature rises above 100° or 101° F. Subsequently, the dressing should be changed every two or three days. The wound should be allowed to heal from the bottom, and if healthy granulations are slow in forming, they may be stimulated by a mixture of balsam of Peru, iodoform, and guaiacol.

The wound may be allowed to close, in some cases, within two or three weeks, while in others it becomes necessary to keep it open for two or three months. The operation itself is not dangerous when properly performed; the danger lies in not instituting operative procedures early enough, before brain complications occur.

THE EPIDEMIC OF DENGUE AT HOUSTON, TEXAS; CLINICAL REPORT OF CASES.

By I. B. DIAMOND, M.D.,
of Houston, Texas.

During the epidemic of so-called dengue fever which prevailed extensively here and elsewhere throughout Texas last summer, different opinions were expressed as to the true nature of the disease. A number of the symptoms appeared analogous to those observed in yellow fever, so that a differential diagnosis between the two affections was often difficult. A number of such cases, which I deem worthy of publication, came under my observation.

Out of 71 cases, observed and treated, 23 were in children; to these latter I will refer later. In the majority of cases the onset was sudden. In many, a severe chill marked the beginning of the attack, and it was not uncommon to observe a succession of chills one after the other. The chill was soon followed by backache, pains in the head, bones, joints, and muscles, and also by loss of appetite, nausea, and vomiting. Nausea was constantly present in the majority of cases. The tongue was coated white, and frequently redness around the edges was observed. The bowels, as a rule, were constipated and difficult to move by medication. The face was flushed, skin dry, and conjunctivæ injected. The elevation of temperature was gradual, and during the course of the affection ranged between 103° and 106° F., and the pulse 100 to 120 per minute.

In the majority of the cases it was noticed that the pulse gradually became slow on the second and third day, frequently as low as 50 beats per minute, while the temperature remained as high as 103° F., or even higher. This want of correlation between pulse and temperature was a marked feature in my cases. The urine in many cases was of light color, and micturition frequent and painful; while in others it was high colored and diminished in quantity. Albumin was present in a few cases. Unfortunately, no systematic examination of the urine was made. While albumin was sometimes absent on one occasion, it would not infrequently be found on subsequent examination. During the thirty-six to seventy-two hours following the onset of the affection the pains constantly increased in severity, especially those in the head and back. The pains were described by many patients as tearing and crushing. At this stage the patients felt very uncomfortable, became exceed-

ingly restless, and unable to sleep. Slight delirium was noticed in a few cases. Cold feet and chilliness were often complained of during the fever. After the disease reached its height, usually on the third day, the fever began to abate and the pains to subside, leaving the patient in a prostrated condition. In a number of my cases an eruption soon appeared, followed again by a second paroxysm, with pain, fever, etc. Itching was often present, associated with a tense and hot skin, especially of the palms of the hands and soles of the feet. The eruption, as a rule, was punctiform, deep red in color, and the size of a pin-head. In a few instances it was more or less diffuse, and in one case it had the typical appearance of urticaria. The eruption continued but a few days, when convalescence, often protracted, began. Nearly all cases resulted in recovery. Extreme debility, mental and nervous exhaustion, were marked in the majority of my cases. Weakness and pains in the lumbar region, which became aggravated on walking, were frequently complained of during convalescence. Appetite soon returned, and in many it even became ravenous. A peculiar and bitter taste in the mouth, especially on taking food, was often complained of, and this symptom usually continued some time. Cramping pains in the abdomen, described as colicky in character, and continuing for several weeks, were also complained of by many patients.

An icteroid hue of the face and conjunctivæ during convalescence was noticed in a number of my cases. In several cases minute hemorrhages, which gradually disappeared, were observed in the conjunctivæ. In six cases vomiting was a prominent symptom, and continued throughout the course of the affection. In these cases weakness was marked, pulse slow, tongue red and dry. In one, that of a woman aged fifty years, gastric hemorrhage occurred on the second day. The blood was mixed with the vomit. The matter from the stomach usually consisted of bile and mucus. Nothing was retained by these patients for any length of time.

Pains in the abdomen were often a prominent symptom. In some it was referred to the pit of the stomach, in others, to the region of the appendix. In one case, that of a young married woman, the pain was referred to the region of the gall-bladder; in another, in a young man, there was constant pain in the left inguinal region, radiating down the left leg. Another feature in this case was complete obstruction of the bowels during six days; the patient vomited considerably, his temperature ranged between 100° and 104° F., and the pulse from 80 to 100 per minute. During this time he complained of severe frontal headache. I may state that medication and enemata were employed without avail. The constant application of ice was resorted to with good results. It was used in all cases in which pain in the abdomen was constantly present.

In two of my cases marked jaundice was present throughout the attack. Menstruation occurred in a young woman during her illness; it had more the character of a hemorrhage than of menstruation. The discharge was dark red, almost black in color, and continued several days. This was also accompanied by pain in the lower part of the abdomen.

Relapses followed in seven of my cases after an interval of from one to five weeks. The relapse was usually more severe than the primary attack, as is illustrated by the following case:

Mrs. N., white, aged twenty-eight years, the mother of three children, and at the time of the attack in the ninth month of gestation. She had recently recovered from a mild attack of the disease under consideration. On November 2d, twelve days later, she was taken with a severe chill, which was repeated several times during the night. The first chill was followed by cephalalgia, backache, and severe pains in the abdomen. The tongue was coated and red around the edges; nausea and vomiting were present, as well as constipation; temperature, 105° F.; pulse, 110. The face was flushed and the eyes injected. These symptoms continued until the third day, November 5th. During the night of the fifth she became delirious; temperature, 106° F.; pulse, 110. There was sordes of the lips, and the tongue was swollen and red. The pains increased in severity. Fetal movements had not been observed for several days, which, of course, indicated the occurrence of fetal death. On the following morning she was taken with true labor pains, and after several hours gave birth to a dead child. Undoubtedly the fetus died either as a result of the high maternal temperature or from infection, transmitted from the mother, as the infant was not cyanosed when born. The mother had fever for several days following parturition; temperature ranging from 101° to 104° F.; pulse about normal. On the following day she had a moderate hemorrhage from the nose which lasted several hours. The tongue continued red and dry. Diarrhea followed and lasted during the next three days, the patient having from ten to twenty evacuations daily. She gradually improved after the ninth day, and finally recovered.

In one of my cases there were marked renal symptoms and general dropsy. The urine was dark and smoky, and loaded with albumin and cast, as well as blood-corpuscles in different stages of degeneration.

In children the disease ran a comparatively mild course. In twelve a distinct rash was present. The youngest child attacked, in whom the rash was also present, was an infant three weeks old. The mother, as well as the other members of the family, had the disease during the same week, so this was undoubtedly a true case of dengue. In two children the

affection was at first mistaken for measles, and in another for scarlatina. The rash usually appeared earlier than in adults. Constitutional disturbances was not so marked as in older patients. Chilly sensations were occasionally present. The fever was usually slight. Headache was constantly present. The face was flushed and conjunctivæ injected. The tongue was coated, appetite lost, and vomiting was an occasional symptom. As in adults, the bowels, as a rule, were constipated. The children were restless, and preferred to walk about during the illness.

In four cases an icteroid hue of the face and conjunctiva was observed, and in two there was marked jaundice. In these cases the attack was more severe. Pains in the abdomen were usually complained of. In children the disease was first manifested by the occurrence of a chill, following which the temperature ranged from 100° to 103° F.; pulse 100 to 120. A general hyperesthesia of the skin was also noticed. When touched the child would cry out as though in pain. In three cases the attack resembled typhoid fever, and continued over two weeks. Swelling and redness of the right knee and ankle developed in a boy of twelve years of age during the attack, and continued five days. This is the only instance in which this symptom was observed, although it has been described as one of the features of dengue.

The treatment was entirely symptomatic. In many instances treatment was not necessary. The bowels were usually moved by means of small doses of calomel, followed by a saline. Quinin was at first administered, but its use was soon abandoned. The main treatment was directed to the relief of pain and the reduction of temperature. For this purpose codein, in combination with acetanilid and caffein citrate, often sufficed. Occasionally morphin was necessary. Applications of ice proved very valuable in causing a reduction of fever and for the relief of the pains in the abdomen and head. For sleeplessness, bromids were given, but often with but little effect. In such cases whisky had a favorable action, and was freely given. For the nausea and vomiting small doses of creosote proved beneficial, while in more severe cases the hypodermic administration of morphin became necessary. During convalescence strychnia and preparations of phosphorus for the nervous prostration proved very helpful.

The Cuvier Prize Awarded to Professor Marsh.—The Cuvier prize of the Academy of Sciences, Paris, value 1500 francs, has been awarded to Professor Marsh of Yale University. This prize is awarded every three years for the most noteworthy work on geology or on the animal kingdom.

FOREIGN BODIES IN THE CORNEA.

By EDWARD JACKSON, M.D.,
OF PHILADELPHIA;
PROFESSOR OF DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC; SURGEON TO WILLS' EYE HOSPITAL.

A PATIENT'S statement that there is a foreign body in the eye is not altogether reliable, for the presence of inflammation, swollen conjunctival veins or papillæ, or an abrasion of the conjunctiva, may all give rise to the same sensation. Even when a foreign body has previously been present the resulting injury to the cornea or conjunctiva may cause a similar sensation, though the removal of the invading material has already been effected. On the other hand, should such a body be so deeply embedded in the cornea that it does not give rise to irritation of the conjunctiva, it may remain for several hours or even days without causing any discomfort whatever, and the circumstances under which it gained entrance may be quite forgotten. The symptoms of inflammation come on gradually, and the distinctive sensation of a foreign body may be absent; so that either a positive or negative history may be equally misleading.

Hyperemia, when present, is very suggestive of a foreign body in the cornea, though it will usually require some hours or even days for its development. It is always partly pericorneal. If the foreign body is located near the center of the cornea the pink discoloration will extend around the entire limbus, if it is located near the margin the hyperemia will be greatest in the adjoining portion of the limbus. On the other hand, if the foreign substance is embedded in the conjunctiva or lid the redness will be irregularly distributed.

The diagnosis, however, rests upon the results of careful inspection. For this purpose either oblique illumination with a lens or diffuse daylight is necessary. In the use of the first the cornea should be strongly illuminated, the condensing lens being so held as to concentrate the light upon it, and the eye should be viewed from different points. A foreign substance of dark color may be best detected against the iris, while one which is light in color will be most easily found when it is strongly illuminated and seen against the dark background of the pupil. With inspection by direct daylight, the surgeon's eye should be so placed that it will receive the reflected light from different parts of the cornea. An irregularity in the corneal surface, such as is caused by an abrasion or the presence of a foreign substance, will cause a corresponding irregularity in the reflection. Slight irregularities of the corneal surface may, however, be filled with mucus, thus concealing any body which may be present. To prevent this the cornea should be wiped with absorbent cotton.

A substance embedded in the cornea may also be detected by means of the ophthalmoscopic mirror, a strong convex lens being placed behind it. Thus, on viewing the cornea from different directions, the foreign body will in some position be brought in front of the illuminated pupil and will appear black against the red background.

When a body is allowed to remain in the cornea, the resulting inflammation gradually increases and suppuration usually occurs. By this process the invading substance is loosened and either rubbed off by the lids or washed away by the lacrimal secretion, after which the ulcer slowly heals. In a few cases there seems to be an active proliferation of tissue, mostly epithelial, which covers the foreign body. In this way it may be retained and be the cause of an inflammation which may continue weeks or months. In such a case the tissue covering the foreign substance appears dry and white, and to it runs a sharply defined area of conjunctival or subconjunctival hyperemia, resembling that which is typical of a fascicular keratitis. A series of cases in which foreign bodies were thus retained in the cornea for periods varying from three weeks to eighteen months have been reported by the writer (*Brit. Med. Jour.*, June 8, 1897). Extremely minute foreign bodies, so retained, gradually making their way with the lymph currents toward the center of the cornea, are by some authorities regarded as the cause of pterygium.

It is hardly necessary to say that treatment implies the prompt removal of the cause of the trouble, with the single exception of powder stains or "grains" in the cornea, which have been present long enough to have become somewhat disintegrated and to have ceased to be a cause of irritation or inflammation. Any damaged corneal tissue should also be removed; for if left to come away of itself it will result in a delay in the healing process. Thorough treatment also implies removal of the brown stain which sometimes surrounds a foreign body in the cornea. I have never observed a case in which the presence of such stained tissue was permantly tolerated.

Removal of the foreign substance is usually accomplished with the aid of a spud. Varying forms of this instrument have slight advantages in different cases. The instrument which seems to me most generally useful is straight with a rather small or pointed end, not sharp, but still more nearly approximating a point than many of the spuds to be found in the shops. This instrument should not be used as a scraper, and removal of the foreign body will not be facilitated by sudden "digs" made with it. It should be carefully and accurately placed in contact with the cornea, by the side of the body to be removed, and then pressed rather firmly into the tissue until, by a wedge-like action, the body is forced out, the spud passing under it. To easily accomplish this it is necessary that the surgeon's hand and the patient's eye be as steady as possible.

Previous to attempting removal the eye should be thoroughly anesthetized by means of one or two instillations of a four-per-cent. solution of cocain, or a one-per-cent. solution of holocain. Meanwhile, the patient should be accustomed to the presence of the fingers and the instrument before the eye by touching the organ in question with the fingers and by moving these close in front of it until it is demonstrated that there really is nothing to fear. The patient should be urged to look at some object steadily, regardless of what is being done to the eye.

When the particle to be removed is a splinter of wood or a piece of grass or grain more or less firmly embedded, it may be necessary to deal with it much as one deals with a splinter embedded in the skin. A small needle or the point of a Graefe knife should be passed down alongside the splinter, to its end if possible, and then made to cut outward, so as to provide a free opening. The spud may now be used to turn out the foreign body in the ordinary way.

"Powder grains" in the cornea during the early stage of irritation and inflammation should be removed by means of the galvanocautery. Such particles are not actually "grains," but bits of charcoal diffused through the corneal tissue; and they can only be removed by destruction of the tissue involved. Any attempt at their removal with needles or knives favors the extension of infection and inflammation.

When a foreign body is deeply embedded in the cornea and extends through into the anterior chamber, its removal is a more serious matter. In such cases it is usually found that the escape of aqueous humor has left the eyeball comparatively soft, and allows the iris and lens to fall forward and perhaps to come in contact with the foreign body. In such cases early removal is particularly important. Until the time of operation the eye should be kept perfectly quiet, so that an opportunity is furnished for the accumulation of aqueous humor and restoration of the anterior chamber. The eye should, of course, be anesthetized by means of a strong solution of cocain. A broad needle, not lance-shaped or like the keratome, but one gradually tapering to a width of three millimeters at a distance of eight to ten millimeters from the point, should be thrust through the cornea near the foreign body, so as to pass beneath it, and the point made to engage again in the cornea, but not to entirely perforate it. Having the needle passed back of the foreign body, so as to prevent it from being pushed

into the anterior chamber or from injuring the iris or lens, removal of the body may be easily accomplished.

In all these manipulations some sort of a magnifier will prove of great assistance. The binocular magnifier, described by me in the *Archives of Ophthalmology* for April, 1897, is the most satisfactory; it gives the greatest enlargement compatible with sufficient working space between the lens and the eye, and offers the benefit of binocular vision without any excessive strain of convergence.

ARTERIOSCLEROSIS AS A CAUSE OF KIDNEY DISEASE.

BY EVERETT J. BROWN, M.D.,
OF DECATUR, ILL.

MOST observers now agree that the kidney changes accompanying a general arteriosclerosis are secondary to the constitutional affection. On the other hand, there are writers who still hold to the theory that all sclerotic changes in the blood-vessels follow a primary fibrous change in the kidneys; that in most cases of general arteriosclerosis the most serious pathologic results are manifested in the kidneys, heart, brain, and liver. Bright himself noticed that chronic renal disease was often associated with hypertrophy of the left ventricle, and all subsequent investigators have confirmed his observations. Grainger Stewart found cardiac hypertrophy in forty-six per cent. of the cases of granular contracted kidney; Loomis, in sixty per cent; Dickinson, in seventy-four per cent., and Galabin in eighty per cent.[1]

Strumpell is inclined to regard the effect of a general arteriosclerosis upon the kidneys as more important than the changes induced by it in the heart and brain, and he only mentions the "granulated" senile kidney as being largely due to atheroma of the renal arteries. In writing of the etiology of arteriosclerosis, he classes nephritis with excessive use of alcohol, syphilis, rheumatism, gout, and lead-poisoning as the cause of the affection in question. Regardless of whether the kidney lesion is primary or secondary, there is no doubt that renal symptoms occur in the majority of cases of general arterial sclerosis. In nearly all autopsies, according to Osler, in which this disease is found there are also evidences of kidney degeneration—either a diffuse or localized sclerosis of the interstitial tissue. It is seen in a typical manner in the senile form of nephritis, and it not infrequently develops earlier in life as a result of chronic diffuse nephritis. Osler further states that it is difficult to decide clinically whether the arterial or the renal disease is the primary affection.

The degeneration which occurs in the general arterial system is also found in the arteries of the kidneys, and in all cases there is an excess of fibrous tissue. Gall and Sutton noticed the predominance of the fibrous change in the external coat of the arteries, in the form of a fibroid hyperplasia, which they call a "hyalin fibroid transformation." The internal coat was also sometimes markedly thickened, and the muscular coat showed a relative increase in thickness, though in some parts the latter was wasted and degenerated. In forty post-mortem examinations in cases of chronic renal disease, Loomis found, as regards the systemic and renal arteries, that the external coat was thickened in many cases; it alone was diseased in twelve instances, and the muscular coat was thickened in five. In twenty-one cases in which the kidneys were involved this fibrosis could not be distinguished from that of the neighboring interstitial tissue or from that about the glomeruli. From this it is seen that the morbid changes are external to the arteries as well as in their walls.[1]

In regard to the effects of chronic renal disease on the heart and blood-vessels, Dickinson says:[2] "There occurs a hypertrophy of the cardio-arterial system which is unusual from its origin to its termination, and comprises not only the ventricles and arterioles, but affects also the intermediate arteries of every size." He has further shown from post-mortem evidence that the arteriosclerosis is more constant than cardiac hypertrophy in relation to chronic renal disease; on the other hand, in some cases of renal involvement the arteries are perfectly normal while the cardiac disease is marked.

The presence of renal disease may be suspected in every case in which the four pathognomonic signs of general arteriosclerosis are present. These signs are: Increased arterial tension, palpable thickening of the arteries, hypertrophy of the left ventricle, and accentuated aortic sound. Even before direct evidence of disease of the kidneys is presented its existence may be suspected whenever a forcible heaving of the left ventricle and increased tension of the blood-vessels are noticed.[3] On the other hand, in many cases of arteriosclerosis there are few symptoms except those of the renal disease.

In a typical case of general arteriosclerosis with involvement of the kidneys the symptoms are somewhat as follows: The patient is a man, over forty years of age, who presents a history of having always enjoyed robust health. His appetite is good, often excessive, and his diet has consisted largely of meat and other highly nitrogenous foods. His occupation is such as to give him little opportunity for physical exercise, and his inclinations in this direc-

[3] Sanson, *loc. cit.*

tion are slight. He has a healthy appearance, possibly a florid complexion, and on slight exertion becomes short of breath. He has some dyspepsia, headache, or maybe a recurring bronchorrhea. At night he finds it necessary to rise twice or oftener to void his urine, which is pale and increased in quantity, but quite clear and free from sediment. The specific gravity of the urine is low—1012 to 1018—and there is a diminished amount of urea and and a small amount—often a mere trace—of albumin. Microscopic examination reveals the presence of a few small hyalin casts. The pulse is full, hard, and easily compressed, and the artery is palpable between beats, and even when it is firmly compressed with the finger its outline can still be felt below the point of pressure. At the aortic interspace the second sound of the heart is distinctly accentuated, and at the apex the pulsation is abnormally strong, and is noticed lower down and to the left, showing the presence of cardiac hypertrophy.

Such a case as has just been outlined requires years for its development, and evidences a constant progression toward death, either from uremia or one of the concomitants of the accompanying arteriosclerosis, such as apoplexy from a ruptured cerebral vessel, an embolus, rupture of a thoracic aneurism, gangrene from an obliterating endarteritis, or a moist gangrene from embolic occlusion of the large artery of an extremity.

In treating old men and women for the various pathologic accompaniments of senility, all physicians have noticed that although the urine of such patients, after frequent examinations, shows nothing abnormal except, perhaps, a low specific gravity and polyuria, yet just before death they develop symptoms of uremic poisoning and suppression of urine, and when the kidneys are examined post-mortem they are found to be contracted. The nephritis of arteriosclerosis is a much more common disease than is usually supposed, and the clinical picture is not always as pronounced as my description of a typical case would imply. The morbid picture is often composed of a series of vague and indefinite symptoms which are difficult of interpretation. The changes in the heart and circulation often produce subjective symptoms referable to the kidneys long before any are noticed by the physician. A life-insurance examination may perhaps reveal an unsuspected nephritis. Disturbances of vision lead many such patients to consult an oculist, who is the first to discover changes in the fundus of the eye pointing to a kidney lesion, an indication which is confirmed by a subsequent analysis of the urine.

The prognosis depends upon the age of the patient, the etiologic factors in the disease, and especially upon the stage of the process affecting the renal tissues. Mahomed[1] describes a pre-albuminuric stage of Bright's disease, to be detected by the increased arterial tension before the commencement of any kidney change or the appearance of albumin in the urine. By carefully observing the degree of tension of the radial artery, much valuable information in regard to the progress or arrest of the disease may be obtained, for with the diminution of dropsy and albumin the artery will be found more compressible, while with the increase of arterial tension there will be an increase of albumin, increased hypertrophy of the left ventricle, increased edema, retinal hemorrhages, and uremic symptoms. As the kidney lesion is only one of several morbid elements in this disease, the prognosis depends much upon the ability of the other organs to continue the performance of their functions. Many cases terminate with a predominance of nephritic symptoms, such as dropsy and uremia, while others present a perfect clinical picture of chronic valvular heart disease with a loud blowing murmur at the apex, which may deceive the practitioner. Other patients die from cerebral hemorrhage, sudden rupture of a thoracic aneurism, or from gangrene of the extremities. In some cases a severe bronchitis with marked emphysema develops, and often in the senile form of the disease the cause of death is ascribed to "old age," not only by the laity, but by physicians as well.

The following cases illustrate two forms of general arteriosclerosis, in one of which there was a predominance of renal symptoms, and in the other prominent renal manifestations, with a fatal termination, immediately due to circulatory changes.

Case I.—H. B., farmer, aged forty-nine years. December 22, 1896, examination showed the presence of general arteriosclerosis. The pulsation of the temporal and radial arteries was very forcible, and the vessels themselves were very tense and easily palpable. The area of heart-dulness was increased, and the apex beat was in the seventh interspace. There was general edema, especially marked in the feet, and some dyspnea and insomnia. Constantly recurring headache had been a feature of this case for several years. At this time he was still able to continue at his daily work. He arose three or four times every night to urinate. The result of the analysis of the urine was as follows: Color, pale yellow; total quantity, 75 ounces; reaction, acid; specific gravity, 1018; albumin, three-fourths volume. The microscope showed the presence of many large and small granular and hyalin casts. Sugar was not present. By means of a proper diet and the free administration of eliminants the dropsy was much improved.

[1] Mahomed, *Medico-Chirurgical Trans.*, p. 197, 1874.

CASE II.—Mrs. A. S., farmer's wife, aged forty-seven years, was in the midst of the climacteric. At the time of examination she menstruated every three or four months. She complained of universal pains, frequent headache, and palpitation of the heart. There was some swelling of face and extremities, much dyspnea on slight exertion, bronchitis, pain after eating and flatulence. Physical examination showed a systolic murmur at the apex, and increased area of heart-dulness. The apex beat was to the left of the nipple line. The palpable arteries were tense and cord-like, but not tortuous. The specific gravity of the urine was 1018. There was present considerable albumin, but no sugar. Patient was kept under observation four years, and by means of digitalis, tonics, and eliminants she was made more comfortable. Much of the edema and dyspnea disappeared. Finally, however, she was seized with a sudden pain in the left leg, the left foot became cold, the tibial arteries ceased to beat, and death occurred within a few days from moist gangrene due to the lodgment of an embolus at the bifurcation of the popliteal artery.

NEW INSTRUMENT.

FORMALDEHYD DISINFECTION.

BY JACOB R. JOHNS, M.D.,
OF PHILADELPHIA.

THE difficulty attending the application of formic aldehyd to general disinfection has led to the devising of a score or more lamps and generators supposed to meet the indications. Many of these, because utterly devoid of merit, have never come into prominence, while others, which possess some value and a more or less restricted field of usefulness, are quite well known. No less than seven different forms of apparatus were exhibited at the last meeting of the American Public Health Association in Philadelphia. The difficulty appears to lie in the liberation of the gas in its most active form in sufficient volume and with sufficient rapidity to overcome all unavoidable loss through holes and crevices, and thus do the work thoroughly.

Three methods requiring different apparatus are in vogue. In the first and oldest, the gas is generated directly from wood alcohol upon the principle of retarded combustion; in the second, it is liberated from pastilles of paraformaldehyd exposed to the action of flame, and in the third, the gas is derived from an aqueous solution of known strength. In the first two classes the apparatus must be confined in the closed apartment which is being disinfected, where it is a source both of danger and uncertainty of action.

If lamps burning wood alcohol are used, the operator can never know what per cent. of alcohol is completely consumed and what is changed to available formaldehyd gas. The volume of gas generated is always uncertain, and never large even when the apparatus is operated by an experienced chemist. In the effort to obtain sufficiently large volumes of gas during the same period of exposure the second and third methods have been devised. In the third method a new difficulty was encountered, that arising from polymerization, which promptly arrests the process.

The failure of the last process mentioned led Trillat and others to devise a means for generating the gas under pressure. This requires an extremely bulky apparatus and introduces a new element of danger, that from explosion. The latter element and the fact that polymers are formed led to the employment of the polymerized product in pastilles, which, while it gives better satisfaction than is obtained from alcohol lamps, affords but little gain in either the volume of gas or the rapidity of elimination.

Another method, intended to overcome all the foregoing difficulties, is that used in the apparatus here shown. (Fig. 1.) The method is both simple and novel. The apparatus consists of a copper coil placed over a Swiss heating lamp and beneath a receiver in which is placed commercial formaldehyd, an equeous solution containing forty per cent. of formic aldehyd gas, and ten per cent. of methyl alcohol to make the solution permanent. A small valve protects the opening from the receiver into the coil. When the latter is red hot the valve is opened to admit a small stream of the formaldehyd solution into the coil. Instantly it is vaporized, and the vapor containing the free gas is heated to upward of 1000° F. as it passes through the coil and a short hose through the key-hole, or other suitable opening, into the room to be disinfected. The apparatus is always on the outside of the apartment being disinfected, and under constant observation. The process does not permit of the formation of polymers, nor present the least danger of explosion, since the gas is not generated under pressure. It is especially adapted to apartment disinfection. With such an apparatus one man can easily disinfect upward of twenty apartments per day.

FIG. 1.

Formaldehyd generator.

This method was introduced by the Sanitary Construction Company of New York, and the apparatus is made by the H. K. Mulford Co. of Philadelphia.

MEDICAL PROGRESS.

The Parasites of Malarial Fever.—THAYER (*Yale Med. Jour.*, January, 1898) gives the results of careful observations made in 1719 cases of malarial fever. He finds three distinct parasites; the tertian, the quartan, and the estivo-autumnal. No transitional forms have ever been observed.

The tertian parasite, in its earliest stages, is a small body lying within the red blood-corpuscle. It is possessed of active ameboid movements, but on account of its lack of color is observed with difficulty. However, it is readily detected by the practised eye, even in fresh unstained specimens. As the parasite grows it accumulates fine pigment granules which at the end of thirty-six hours have gathered together at one point, usually the center of the organism. The parasite next undergoes sporulation, and is separated into its central pigment clump and a surrounding mass of small, round, hyalin bodies, which are complete young parasites ready to attack fresh red blood-corpuscles. The life history of a parasite occupies forty-eight hours, and sporulation takes place in all the parasites at the same time, thus producing the febrile paroxysm in the patient.

The quartan parasite, in its early stages, greatly resembles the tertian, though its ameboid movement is weaker. As it grows the pigment granules are larger and darker than those of the tertain, and are inclined to gather in the periphery. Sporulation proceeds along symmetric lines, the parasite dividing into from six to twelve regulariy arranged radial leaflets. The cycle of development requires seventy-two hours.

In both tertian and quartan infections more than one group of parasites may be present in a patient, giving, in double tertian and triple quartan infections, a chill every day. In double quartan infections there will be a chill upon two successive days and none upon the third.

The estivo-autumnal parasite is associated with fever which is more or less irregular. This form is rarely found in the milder malarious districts. The parasite is a biconcave disc with a well-marked central depression, so that it may appear like a ring. It is smaller than the tertian and quartan parasites and materially differs from them in the fact that it is usually found in the circulation only in its earlier stages of development. The later stages of development may be observed in blood aspirated from the spleen. This procedure is not without danger and should be carried out with the strictest aseptic precautions. After a certain length of time, varying from five days to two weeks, there appear in the circulation crescentic bodies with sharp refractive outlines containing pigment. If these are closely watched filaments may sometimes be observed to burst out from the parent cell and sometimes to break away from it to rush off alone across the field of vision. In the estivo-autumnal parasite sporulation does not occur in groups and hence the irregularity or continuousness of the fever.

The existence of these three distinct types of parasites has been proved not only by clinical observation, but further by careful inoculation experiments. Fresh blood from an infected patient, if introduced under the skin of a healthy man will invariably reproduce the same type of fever. There are still many questions in connection with this subject which cannot be definitely answered. Why should the process of sporulation cause fever? This is presumably because some toxic substance is set free from the parasite itself. The significance of the flagella has also puzzled observers. Recently MacCallum observed the penetration of a free flagellum into one of the non-flaggelate parasites. This observation strongly supports the idea previously advanced that flagellation and fertilization are intimately associated processes. At any rate, the old idea that flagellation is a degenerative process seems absolutely untenable.

As to modes of infection, there are at present considered to be three, *viz.:* by air, water, and by the bites of insects, especially the mosquito. The last is at present most popular. At the close of this most interesting article Thayer insisted upon the importance of the discovery of the parasite in the blood as the only diagnostic sign of malarial infection; a sign in many ways parallel to the demonstration of the tubercle bacillus in phthisis, or the Klebs-Löffler bacillus in diphtheria.

Results of Postural Drainage.—BURRAGE (*Annals of Gyne. and Pediat.*, January, 1898) has of late employed the postural method of draining the peritoneal cavity after abdominal operations, described by Clark in the *Johns Hopkins Hospital Bulletin* of April, 1897. This method consists in flushing the peritoneal cavity with sterile salt solution, wiping it dry with gauze, and then introducing from one to two pints of sterile salt solution. The abdomen is then closed and the foot of the bed raised eighteen inches, thus favoring a flow of fluid from the pelvis to the diaphragm, where absorption of liquids contained in this great lymph-sac proceeds with the greatest rapidity. By the use of this method it is possible in many cases to close the abdomen under circumstances in which drainage is usually considered necessary. Clark said, in fact, "the greatest safety lies in closing the abdomen without drainage except in cases of purulent peritonitis, or in operations in which there has been extensive suturing of the intestines, and also in a few other rare conditions."

The twenty-seven patients which Burrage mentions as having been treated by this method all recovered, although in this respect the new treatment did not differ much in result from that previously used in the same hospital in 167 celiotomies performed during the last eighteen months, in only one of which was there a fatal termination. In the new method it is well to keep the foot of the bed elevated at least thirty-six hours. The salt solution increases the amount of urine and diminishes thirst. Vomiting is facilitated by elevation of the foot of the bed. Swallowing is rendered more difficult, but is still easily possible if slowly performed. There is less nausea and less abdominal distention and pain. In two very fat women there was some embarrassment of respiration. The writer expressed himself as well satisfied with the new treatment, which he considers a distinct advance in abdominal surgery.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE	$4.00
SINGLE COPIES	.10

SATURDAY, MARCH 12, 1898.

THE BACTERIOLOGY OF RHEUMATISM.

ABOUT ten years ago it was announced by Bordas that he had discovered the micro-organism of acute articular rheumatism, and attention was called to his claims by an editorial in the MEDICAL NEWS. He asserted that the organism which he had isolated possessed certain definite bacteriologic characteristics, and that if it was injected into the body of the lower animals they immediately suffered from inflammatory joint affections, which in every way resembled those commonly seen in acute articular rheumatism. It was also stated that this micro-organism, which Bordas asserted was the cause of acute articular rheumatism, was peculiarly susceptible to salicylic acid, and so it was pointed out, if we could believe in this research, that the explanation of the value of salicylic acid in acute articular rheumatism had at last been discovered.

Whatever promise, however, was held out by this research was taken away from us by the failure of other investigators to confirm its results, and while the profession has become, with each succeeding year, more and more convinced of the fact that acute articular rheumatism is distinctly an acute infectious disease, definite statements as to the character of the infecting micro-organism have not been forthcoming. In this connection, therefore, a more recent research (*Société de Biologie*, July, 1891) which was published by Dr. Achalme of Paris, is of considerable interest. He claimed to have demonstrated a bacillus which he obtained in patients suffering from acute rheumatism, and he described various means of differentiating it from other micro-organisms of similar appearance.

Since this paper was published, Riva, Cheosteh, Michaelis, and Triboulet and Coyon have carried the investigation still further, and the latter claim that an elongated coccus found in pairs, or grouped in chains at times, is responsible for the malady. It is an anaerobic organism, easily cultivated in bouillon or ascitic fluid and is easily stained by thionin, but it is not discolored by the Gram method. These investigators assert that this is the real organism of rheumatic fever, and that the bacillus of Achalme is found as a complicating infection in certain cases. Unfortunately, as we see so often among other researches in the early stages of our knowledge concerning infectious maladies, these investigations of Triboulet and Coyon have in turn been criticised by other bacteriologists, who assert that certain staphylococci, which are in every way comparable with the coccus which it is claimed is the cause of acute articular rheumatism, are found in rheumatic cases, and Singer of Vienna has asserted that acute rheumatism is only a form of acute septicemia without a specific microbe. Whatever may be the truth of the claims put forward by these various investigators, practising physicians must watch with interest any conclusions arrived at in regard to the bacteriology of a malady which is a millstone about the neck of scientific medicine.

THE DETERMINATION OF SEX.

IT is not improbable that Professor Schenk, of Vienna, would gladly recall the idle words anent the influencing of sex by giving certain dietaries to the parents, if he knew the kind of company that his ridiculous so-called discovery was to lead him into. Not that he ever said one-tenth of all that has been attributed to him, but it matters not how little escaped his lips, he said far too much. It contributed to the destruction of his scientific reputation; the public press has done the rest. The immediate

result of the propaganda, much more serious than the smirching of the Herr Professor's reputation, has been the development and uprising of "Sex-regulators" all over the country. It is not surprising that the Nutmeg State should furnish a number of them. Its inhabitants have made a record for themselves concerning their shrewdness which has come thundering down to posterity. According to the *Sun*, a Danbury physician declares that not only can he tell the sex of an unborn child, but that he knows the secret whereby it is possible for human beings to produce male or female at will. Oh, enviable Danbury physician! If you are truthfully and accurately reported, please let the male child come often enough to balance the awful disproportion now existing between the adult sexes in your own State; and please, furthermore, after the accomplishment of this worthy work, for which woman, particularly spinster woman, will rise up and call you blessed, transfer your presence and remain sufficiently long in New Hampshire to allow the evidence of your power, mysterious and concealed in the intricate recesses of your concept center, to show itself sufficiently to at least encourage the forlorn maidens of that deserving State. For ourselves and the West we ask nothing. We are deeply cognizant that the steamship companies are supplying a demand for husbands in "wooly" sections of our country, by dumping in the refuse of semi-civilized Europe, and that they will continue to do so until restrained by Congress, or until they have exhausted the pauper and criminal supply of the Old World, the degenerate Old World. We know, moreover, that the decadent imported male cannot withstand the rigors of the New England climate, and that, therefore, the discouraging disproportion of females there cannot be remedied in this way. Not that there are too many females in New England, there never can be too many. They are only proportionately too many, and it is this that we ask the doctor with the secret to set right. We confess to a fear that our petition will be of no avail because the concluding sentence of the report which we quote from the *Sun* is portentous, to say the least. It reads: "The doctor is willing to impart his knowledge to families of which he is the regular physician." Let those who are tired of the sameness of sex in their progeny enroll themselves at once, for this physician will soon be the apotheosis of the family doctor and the most conspicuous type of "the busy practitioner."

THE MARINE HOSPITAL SERVICE AND THE ALABAMA SMALLPOX EPIDEMIC.

During the closing days of last year, the Mayor of Birmingham, seconded by State Health-officer Sanders, with the approval of the Governor of Alabama, requested Surgeon-General Wyman of the Marine Hospital Service to aid the local authorities in suppressing an epidemic of smallpox in Birmingham, Alabama. Accordingly, on December 31st, Passed Assistant Surgeon G. M. Magruder, who has had extended experience in dealing with this disease, and who managed in behalf of the Government the colony of negroes who were returning to the United States from Mexico in 1895, and among whom smallpox had broken out at Eagle Pass, Texas, was placed in charge of the undertaking. Dr. Magruder reached Birmingham January 4th, and immediately began a systematic campaign against this widespread epidemic, for it was not confined to Birmingham, but had spread into many of the adjacent counties. It had existed in Birmingham since the middle of July, and the total number of cases recorded to the close of 1897 was 406, out of which number there had been but 15 deaths. The general character of the epidemic had been mild, and the disease confined mostly to the negro population. Indeed, so mild had it been that but little attention was paid to it by the local authorities, and cases in full bloom were occasionally found in persons walking about the public streets. It was not regarded by the class affected as smallpox, but by them was called "African itch."

It appears that there are but few local health organizations in Alabama, and the execution of such laws as relate to protection of the public health is confined to judges of probate for the various districts. During this outbreak no attempts at general vaccination had been made, no restrictions placed upon persons suffering from the disease, and in the outlying counties no effort made to isolate them. As a result, in one county, Lownds, for example, the officials estimated the number of cases which had occurred at from 2000 to 2500, but it was admitted to be a mere generalization without the basis of recorded cases. Facilities for vaccination were provided by the purchase of vaccine by the authorities, who distributed

it among local physicians. The lack, however, of any systematic control of cases resulted in continued spread of the disease, until the authorities had expended all the money available for prophylactic measures, and when at the end of their resources made application, as above stated, for Federal aid in suppressing the epidemic.

Dr. Magruder immediately organized a corps of thirty assistants, and with an ample supply of vaccine virus, began on January 9th, a house-to-house inspection in Birmingham, vaccinating every person when such action was indicated. This course of procedure was immediately adopted, upon the acceptance by the authorities of Birmingham and Jefferson County of aid from the Government. A lazaretto was established upon a military basis, and communication between it and the town was rendered impossible. From January 9th to January 26th, inclusive, 14,751 houses and 58,812 persons were inspected, of the latter 25,042 were vaccinated; 144 houses were disinfected. This work was so efficiently done that the number of cases occurring in Birmingham and other localities in Jefferson County was reduced from seventy per week, as reported on January 15th, to eighteen per week as reported on February 5th. Two house-to-house inspections were made in Birmingham, and a third partial one followed.

It is to be noted that the smallpox exists in the mining districts of Kentucky and Tennessee, and the origin of the epidemic in both States was undoubtedly due to the migration of the negroes employed in the mines of Alabama to similar localities in the two States mentioned.

Information has been received of the prevalence of the disease in at least twenty-five localities in Alabama. The attention of the State health-officer has been called to these facts, but it is said that he has no State funds with which to meet the emergency. It is obviously the duty of each locality to protect itself from the spread of this well-understood epidemic disease; whatever action is taken by the Marine Hospital Service is with a view to prevent its spread to adjoining States. Dr. Magruder, with two or three officers of the Service, acting on orders from Surgeon-General Wyman, is visiting in succession the infected localities and instructing the local authorities how to act. In several instances he has induced the county and town officials to bestir themselves and raise the necessary funds, which it would seem the State health-officer should have done. Expenditures for vaccine and inspection service have been assumed by the general Government only when all other means of meeting them have failed, and only as a part of interstate quarantine procedures.

FAIR CRITICISM AND COMMON SENSE.

THERE is no danger of any misunderstanding among the readers of the MEDICAL NEWS as to its position upon the question of the contagiousness of pulmonary tuberculosis and the importance of placing that disease among those requiring hygienic control. Nor can the strained, artificial efforts of the *Philadelphia Medical Journal* avail to place the MEDICAL NEWS in a false light upon this subject. The readers of the former journal, as well as those of the MEDICAL NEWS, like fair play and honest criticism, and when a contemporary sneaks in at the back door, snatches a sentence from its legitimate connections in a book review, and sets it up as the complete embodiment of editorial creed upon a grave pathologic and hygienic question, some other motive is apt to be ascribed to the act than an honest seeking after truth or the promotion of ordinary ethics. The motive is not far to seek, and the method is not such as becomes honorable criticism.

The medical profession that has read or that may read the quoted sentence as used by the reviewer in discussing the excellencies of Dr. Meigs' volume on the "Origin of Disease" (MEDICAL NEWS, February 26, 1898, p. 287) will not consider itself besmirched by epithets or saddled with false motives. A little common sense is all that is necessary to keep the judgment clear on those points, and he errs grievously who denies the medical profession its share of that commodity—as our contemporary apparently does.

ECHOES AND NEWS.

Cameron Prize Awarded.—The Cameron prize of the University of Edinburgh has been awarded to Professor T. R. Fraser for his researches in practical therapeutics.

Measles on English Warship.—An extensive epidemic of measles is prevailing among the cadets on board the English training-ship "Britannia" at Dartmouth, England.

"Black Blister" in India.—According to the daily papers, an epidemic of "black blister" has broken out in

the State of Hyderabad, and fifty deaths are occurring daily.

A Donation to the Pasteur Institute.—The Pasteur Institute of Paris has received a donation of 50,000 francs from Madame Emile Durand, to be used to promote the study of tuberculosis.

For the Neuralgia of Herpes Zoster.—The pain of both the prodromal and the post-eruptive stages is said to be relieved by the administration of lactophenin in 20-grain doses three times daily.

Dispensary Bill Favorably Reported.—The Senate Committee on Public Health has reported favorably the dispensary bill for New York City, which is designed to prevent the abuse of charity at such institutions.

Biography of Ernest Hart.—The widow of the late Ernest Hart is collecting the correspondence of her husband, together with information bearing upon his public work, to be used in preparing a biography of this distinguished man.

Medical Students in New York.—The recently issued annual report of the Board of Regents of the State of New York shows that there are 4025 students of medicine in the State, an increase of 150 over last year, and a gain of 605 within three years.

Dissecting in Paris.—According to the *Gazette des Hôpitaux* (Paris) there is a great scarcity of dissecting material in the medical schools of the French capital—less than half a body for each of the 1573 students who have been dissecting there this winter.

The Tarnier Prize.—By the will of the late Professor Tarnier a yearly income of 5000 francs is left to the Paris Academy of Medicine. Of this, 3000 francs is to form a prize to be known as the Prix Tarnier, which is to be awarded each year for the best work in obstetrics and gynecology.

New York Medical College and Hospital for Women.—Plans have been filed for a building to be erected on the north side of One Hundred and First Street, near Manhattan Avenue, for the New York Medical College and Hospital for Women. The building will be three stories in height, and will cost $28,000.

Retirement of Dr. Playfair.—Dr. W. S. Playfair will soon retire from the duties of the chair of Obstetric Medicine and the Diseases of Women at King's College, London, as he has reached the age limit. Dr. Playfair has been connected with King's College and King's College Hospital for the past thirty-five years.

Smallpox in Greenfield, Mass.—Several cases of smallpox have been reported in Greenfield, Mass., and fears are entertained that the disease will become epidemic. A joint meeting of the board of health, selectmen, and physicians of the town has been held to decide upon measures for stamping out the disease.

Disinfection with a Vengeance.—It is announced by the publishers of a daily paper in an English town in which smallpox is epidemic, that each copy of the paper "is impregnated with a vaporous disinfectant which not only sterilizes the journal, but converts it into a factor for the widespread distribution of disinfecting influence."

Memorial to Two Naturalists.—A brass tablet has been placed in the biological laboratory of Johns Hopkins University in memory of James Ellis Humphrey, associate professor of botany in that university, and Franklin Story Conant, Bruce Fellow of the university, both of whom died in Jamaica last summer, where they were engaged in making botanic studies.

Klondyke Doctors Must Pass Examination.—According to the *Medical Sentinel*, medical men, who are planning to go to Klondyke in the hope of making a fortune by the practice of their profession, will find that they will not be permitted to practise unless they have passed an examination before the Board of Medical Examiners of the Northwest Territory at Calgary, of which Dr. Britt of Banff, N. W. Territory, is Registrar.

Serum Treatment of Burns.—Tomasoli, an Italian dermatologist, is treating extensive burns by daily injections of an artificial serum composed of a solution of sodium chlorid and sodium bicarbonate with the most excellent results. In an article in the *Monatsschrift für practische Dermatologie*, Tomasoli states that serum from a scalded dog will kill a well one if injected into his veins, but that the fatal result can be prevented by an injection of the artificial serum just described.

State Hospital for Consumptives.—The Senate Committee on Public Health, to which was referred the resolution relating to the establishment of a State hospital in the Adirondack Mountains, New York, for the treatment of pulmonary tuberculosis, has recommended that a joint committee of five, two from the Senate and three from the Assembly, be appointed by the Legislature to make further investigation of this subject; that $1000 be appropriated to meet any necessary expenses of such investigation, and that the committee report its conclusions and recommendations to the next Legislature.

New York Sanitary Code.—A general amendment to the New York Charter, relative to the public health, was recently introduced into the Legislature. It provides that new provisions, amendments, or additions to the sanitary code shall be proposed by the Board of Health and submitted to the Council of the City of New York. Within thirty days the Council shall take a vote upon the adoption of said provisions, and, if adopted by a majority, they shall become law. The present sanitary code shall be submitted, within sixty days after the passage of this act, for adoption or rejection by said Council.

Hospital for Ruptured and Crippled Must Sue City for Funds.—Comptroller Coler is withholding the appropriation of $26,250 made by the Board of Apportionment to the New York Hospital for Ruptured and Crippled upon the ground that the institution has been overpaid $59,169.80

by the city for the board and care of pay-patients. Edward W. Sheldon, counsel for the hospital, contends that the fact that the city paid $150 a year for each of these patients should not debar the hospital from receiving some money from them inasmuch as it costs the institution $250 a year to care for each. Comptroller Coler refuses to pay over the money, and has advised the hospital to bring a friendly suit against the city, saying that the hospital has a right to the money set aside for its use unless the city should show a counter-claim based on the report of the Commissioners of Accounts.

President of Health Board Resigns.—Nathan Straus, president of the New York City Board of Health, sent his resignation to the Mayor on the third inst. In less than an hour Colonel M. C. Murphy was sworn in to fill the vacancy. Mr. Straus, who is interested in a number of business enterprises, pleaded in his letter of resignation that his private business required so much of his time that he found it impossible to continue longer in the service of the city. It is hinted, however, that Mr. Straus' resignation is due to the refusal of the Board of Estimate and Apportionment to allow him sufficient funds to carry on the work of the department according to the accustomed standard. Colonel Murphy was born in Limerick, Ireland, in 1841, and has lived in this country since he was seven years old. He was educated at the public schools, and afterward worked in the composing-room of a daily paper in New York City until the breaking out of the Civil War, through which he served. He was elected to the Legislature in 1866, and for fourteen years represented the lower district of the city in either the Senate or the Assembly.

A New Building for the New York Skin and Cancer Hospital.—On March 5th the New York Skin and Cancer Hospital dedicated and opened for occupancy its new building at the corner of Second Avenue and Nineteenth Street. Addresses were made, there was music, and tea was served by the women of the reception committee. The building is devoted exclusively to cancer and diseases of the skin. The new hospital easily provides seating capacity and treatment-rooms for more than one hundred in its dispensary, and the wards and private rooms are large enough to contain forty-two beds, and at the same time accommodations for the staff and employees. It is the only hospital in the country devoted exclusively to cancer and skin diseases. The new operating-room is spacious and well-lighted, and connected with it are an etherizing-room, an instrument-room, wash-room, and doctors' dressing-room. There is also a well-equipped microscope-room for study, and arrangements for photography. The bath system has an especial value for this hospital. The new building has an equipment of baths unique even among all the luxuriously fitted up and recently built hospitals in the country. Russian and medicated baths, constructed on the best models for cleanliness and efficiency, have been put in to supplement the ordinary baths, and the bath-rooms and appurtenances look particularly pure and inviting, being fitted up in marble, mosaic, and white enameled iron.

The Patent on Antipyrin Expires in July.—In July of this year the antipyrin patent, held by the Hochst color-works, will expire by limitation, it having run its course of fifteen years—the span of life allowed to a German patent. During these fifteen years the monopolists have sold the drug at about $12.50 a pound, but it will, of course, fall considerable in price the moment the manufacture and sale are permitted to competitors. It is anticipated that the price will shortly fall to at least half its present standard, when the usual convention of the principal competitors will probably be called and the inevitable trust formed, leading to a consequent rise in price. It is rumored that a number of chemical works are busy with the manufacture of antipyrin, so as to be prepared with it immediately upon the expiration of the patent.

A New Measure.—A measure which forbids the general distribution of pamphlets, circulars, and other advertisements in which symptoms of diseases are described, is now pending before the Ohio Legislature.

Chloroform Anesthesia by Gaslight.—An unusual accident recently happened in the Catholic Hospital at Herne, in Westphalia. A man who had been shot in the abdomen was brought to the hospital at night and immediately operated upon by gaslight. The operation was very difficult, and the chloroform narcosis was kept up for four hours. As a result of the decomposition of the chloroform by the gaslight, producing powerful chlorinated vapors, two of the surgeons and several of the Sisters of Mercy were overcome, and one of the latter has since died.

Paris Hospitals and the X-Ray.—The Municipal Council of Paris is considering a proposition for the establishment of a radiographic service in each of the hospitals under the control of the Assistance Publique, the service to be under the direction of the medical staff of the hospitals.

Insufficient Hospital Accommodation in Paris.—According to the *British Medical Journal*, the Assistance Publique can dispose of only 7529 beds in the various hospitals. On an average 1200 beds are vacant yearly, for which there are 8200 applicants in a suitable state for admission. M. Lampere, a member of the Municipal Council, advocates the establishment in the environs of Paris of a hospital with 6000 beds, all of which are to be placed at the disposal of the Assistance Publique.

The French Congress of Alienists and Neurologists.—The Congress of the French Alienists and Neurologists will be held at Angers on August 1st and the following days. The questions proposed for discussion are as follows: (1) Post-Operative Psychical Disturbances; (2) The Part Played by Arteritis in the Pathology of the Nervous System; (3) Transient Delirium from the Medico-Legal Point of View.

The X-Ray and a Suit for Damages.—Dr. Frank Boyd of Paducah, Ky., was recently sued by a patient for $10,000 damages on account of a severe dermatitis which followed an X-ray examination. The plaintiff claimed that the

apparatus was carelessly employed, but a verdict was given for the defendant.

Medical Examining Board of the United States Army.—A board of medical officers to consist of Colonel Dallas Bache, Assistant Surgeon-General; Major Walter Reed, Surgeon; Major James C. Merrill, Surgeon; Captain William H. Arthur, Assistant Surgeon, and First Lieutenant Alexander N. Stark, Assistant Surgeon, is constituted to meet at the Army Medical Museum Building, Washington, D. C., on Monday, May 2, 1898, at 10 o'clock A.M., for the examination of candidates for admission to the Medical Corps of the army.

A Preventive of Seasickness.—A compressing belt which it is claimed will prevent seasickness, even in those most easily affected, is being patented by Galliano of Turin.

Fiske Fund Prize Essay.—The trustees of the Fiske Fund, at the annual meeting of the Rhode Island Medical Society, held June 3 1897, announced that they propose the following subject for the year 1898: "The Neuron Theory, as Related to Brain and Nerve Diseases, in the Light of the Most Recent Investigations." To the best essay upon this subject worthy of a premium they offer the sum of $350. Further information may be obtained of the secretary of the trustees, George L. Collins, M.D., 223 Benefit street, Providence, R. I.

Popularity of Glass Eyes.—According to a German authority the astonishingly large number of 2,000,000 glass eyes are made every year in Germany and Switzerland, while one French house manufactures 300,000 of them annually.

Water-supply of Mobile, Ala.—Dr. George A. Ketchum of Mobile, dean of the faculty of the Medical College of Alabama, professor of medicine, has a lasting memorial for his long professional career in the Gulf City's waterworks. To his energy and perseverance also is due the magnificent water-supply of the city. The water is brought from a distance of twelve miles, is pure, bright, and sparkling, and comes with satisfactory pressure. It is realized to-day that no one thing is more important for the health and welfare of a community than a good supply of agreeable and safe potable water. Dr. Ketchum has given such to Mobile, and that alone is a grander monument than stone or bronze could furnish.

CORRESPONDENCE.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

GLIA AND GLIOMATOSIS—BLOOD FINDINGS IN DISEASES OF THE CARDIOVASCULAR SYSTEM—AN INSTANCE OF LABORATORY INFECTION—STUDENT'S INFIRMARY AT THE UNIVERSITY HOSPITAL—NEW SCHOLARSHIPS AT THE JEFFERSON MEDICAL COLLEGE—DR. WILLIAM PEPPER—THE DECLINE OF THE TYPHOID OUTBREAK.

PHILADELPHIA, March 5, 1898.

SIMON FLEXNER, of Johns Hopkins University, during the course of some remarks on glia and gliomatosis, at the last meeting of the Philadelphia Neurological Society, expressed the opinion that the neuroglia, unlike other connective tissues, is probably derived from the ectoderm—a generally accepted view at the present time. He divided glia tissue into two types—embryonal and adult; three varieties of cells are recognized: ependyma-cells, astrocytes, and astroblasts; glia fibers are now known to be separate, and not extensions from the protoplasm of cells, as formerly believed. Speaking of the different types of glioma, Flexner remarked that this growth is now known to be wholly distinct from sarcoma, and that the type of the tumor is dependent upon the type of cells which predominate in it. One variety contains a majority of astroblasts; another variety is chiefly made of astrocytes, and a third variety is composed mostly of ependyma-cells. Rapidly growing tumors show no differentiation between the cells and the fibers, and correspond to the embryonic type; while to the adult type belong those tumors of slower growth which show a differentiation between the fibers and the cells. Gliomatosis was considered in the light of a fault in development, and the relationship between gliomatosis and syringomyelia was thought possible of demonstration by future investigators.

Stengel, at the last meeting of the Pathological Society of Philadelphia, gave an interesting summary of the blood-findings in diseases of the cardiovascular system. These diseases he classed as inflammatory, degenerative, and mechanical. In the inflammatory type the chief characteristics of the blood consist in a variable degree of leucocytosis, reduction in the number of erythrocytes per cubic millimeter, and in the inconstant presence of certain pathogenic micro-organisms. The speaker mentioned, in passing, two instances of a very high percentage of polymorphous neutrophiles in leococytosis—the percentage of these cells in one instance constituting no less than ninety-nine per cent. of the total leucocytes, and in the second instance, 98.5 per cent. In the degenerative type, particularly when there is an accompanying atheroma, the blood examination may reveal the presence of small bits of foreign matter, and of oil-droplets. Concerning the mechanical type, important changes due to inspissation and dilution of the blood are found; very high counts are sometimes present, due to an increased viscosity of the blood and to peripheral stasis. Mitral lesions frequently produce counts of from five to seven million erythrocytes to the cubic millimeter, but a normal or subnormal count is more common in aortic disease.

The infection of bacteriologists while working with virulent cultures is so rare, in spite of the risks sometimes taken, that an instance of genuine self-infection with the Klebs-Löffler bacillus, reported by Riesman in the current number of the *Philadelphia Medical Journal*, is of no little interest. Briefly, the instance reported is as follows: A well-known Philadelphia bacteriologist, while transplanting with a pipet measured quantities of virulent cultures of diphtheria from one flask to another, accidently received some of the culture directly into the back of his mouth; he spat out the mouthful of culture, and, without even rinsing his mouth with water, con-

tinued his work for the day. Two days later he noticed a white patch on both tonsils, from which cultures were then made, and a pure growth of the diphtheria bacillus obtained. Four thousand units of diphtheria antitoxin were then injected, 2000 during the morning, and a like quantity during the afternoon; and the next day 2000 units additional were given, with the final result that the membranous patches became smaller, and disappeared on the fifth day. During the appearance of the membrane there were no marked subjective symptoms. Notwithstanding local application of hydrogen dioxid and other antiseptic agents after the fifth day of the infection, cultures from the surfaces of the tonsils continued to show the presence of diphtheria bacilli for a period of almost three weeks after the total disappearance of all local signs. The incident, apart from its interest as an unusual occurrence, is of some value in determining the period of incubation of diphtheria, which in this case was certainly not more than forty-eight hours, nor less than forty hours. However, the value attached to this point must be more or less modified by the circumstances surrounding the infection, particularly the exceptional virulence of the culture and the quantity and the purity of the infecting agent—all of which conditions would tend to produce evidences of infection more quickly than had the exposure been an ordinary one.

The Provost of the University of Pennsylvania has announced that the various classes of that institution have united to contribute to a fund to provide a special ward in the University Hospital for the exclusive use of the students of the University, who may require hospital care in time of illness or disability. The ward will be known as the "Student's Infirmary," and will be fitted up as soon as the requisite funds for the purpose have been collected.

By the will of the late Dr. Francis W. Shain, who died in Jersey City in 1896, two scholarships, to be known by the donor's name, are to be established in the Jefferson Medical College. These scholarships are to be awarded by competitive examination in the English branches to graduates of the public schools of this city. The sum of $3000 is also left to the Jefferson trustees, the interest of which is to constitute three annual prizes to be awarded to the graduates passing the best examinations in practice of medicine, in surgery, and in physiology, respectively.

Dr. William Pepper, who has been spending several weeks in the South, is expected back next week. The indisposition from which he suffered has been wholly removed by his enforced rest, and he will enter upon his professional duties immediately upon his return.

There has been a decided decrease in the number of new cases of enteric fever during the past two weeks, so much so that hopes are now entertained that the present outbreak has about run its course, and that the city will now settle down to its "normal" number of weekly cases—normal for Philadelphia, but abnormal, decidedly so, for other communities. During the week of March 5th 122 new cases of typhoid were reported to the Philadelphia Board of Health, during which period 17 deaths occurred from this cause. For the week ending February 26th, 141 cases, with 21 deaths were reported. Meanwhile, Councils wrangle over what is popularly known as the "water-snake" bill, or the proposition made by a syndicate to furnish the city at prohibitive terms with a supply of filtered water. The "snake" will probably have been killed by the time these lines are in print, for although it passed with a rush through one branch of Councils, the career of this most extraordinary measure was blocked by some of the more honest members of the other branch. At all events the mayor is pledged to veto the steal should it manage to receive a majority of votes in both branches of Councils. Diphtheria is again on the increase, and measles is everywhere. Of diphtheria, 86 new cases, with 26 deaths were reported this week, as compared with 71 cases and 17 deaths last week. There were 41 new cases of scarlet fever this week, with 2 deaths, against 45 cases, with a single death, last week. And in spite of infection of every sort, in all quarters, Philadelphia may call herself a healthy city, as evidenced by the death-rate reported for last year, recently noted in these columns.

OUR BERLIN LETTER.

[From our Special Correspondent.]

THE EMPEROR'S BIRTHDAY—REACTION AGAINST ANIMAL EXPERIMENTATION BY CLINICIANS—DRINKING-WATER AND THE PRESERVATION OF THE TEETH—THE PASSING OF LANDRY'S PARALYSIS.

BERLIN, March 2, 1898.

ON January 27th Berlin celebrated the Kaiser's thirty-ninth birthday in most loyal fashion. The crowds who gathered near the palace at all times during the day, but especially in the evening, to catch a glimpse of him, were an evident sign of the high esteem in which he is held by most Germans. It has become the fashion for the foreign press generally to belittle him, to point out his overweening vanity, his thorough self-conceit, and his absorption in his own interests and in those of his family. Most of us foreigners who come here have such impressions. Medical men are apt to know something of certain physical defects of the emperor, and to consider them but signs of an organic degeneracy underlying his mental peculiarities. It is quite the fad for the American and English political press to talk in this strain.

I cannot help but think that most of us change our minds when we have learned to appreciate his actions a little better. Instead of absorption in self, one learns to see in him a lively interest in everything that interests the great German nation. He thinks so much of German language, literature, and science, that any personal inconvenience to which he may be put for the encouragement of these seems to count as nothing to him. Medical men who observed his graciousness at the reception to the members of the Leprosy Conference must have been impressed with his lively interest in anything that might protect his people or redound to the glory of German science.

He knew enough of the subject to talk pleasantly, yet interestingly and interestedly, with the representatives of

the various nations. He had the tact to spend a notably longer time with the French representatives than with others. He won everybody by his uncondescending graciousness. There is a personal magnetism about the man which makes those who come in contact with him almost involuntarily do him honor. He went down to Hungary not long ago, where, as a rule, Germans are cordially hated, and completely won the youth of the Hungarian University. The relations between the countries have taken on quite another aspect since. He has not consented to occupy the place of innocuous retirement that somehow it has come to be thought that the ruler of a constitutional monarchy should occupy. He has felt the responsibility of the duties devolving upon him, and has endeavored to show his interest in the vital processes going on in his empire. Duty seems ever to have been a precious word to him, as he has been a model husband and father. His duties as head of the state have involved his public assumption of faculties of state that seemed to thrust him too much into the foreground. He is the head, however, of one of the best-governed countries in the world, and his manifold interests are furthering its development in wonderful ways. Millions are spent on the army and navy, but millions too for the University and a new Charité.

Much more might be said, but at least this must be added: a medical man who has studied a little closely the evident purpose of the emperor to be what he is supposed to be—a ruler of his people—cannot but protest against certain utterly false views in regard to him which seem to prevail among foreign medical men. He is a German of the Germans, but, instead of the weak-minded prince with delusions of grandeur that an English press, jealous, perhaps, because their male rulers for a century have been anything but presentable, would picture to us, he is an eminently sane, thoroughly responsible monarch, from whom every, even the slightest, interest of his empire claims attention.

In certain quarters here in Europe a reaction against animal experimentation is evidently setting in. This department of biology has its place, but that place is evidently not the laboratory of the clinical professor of medicine, nor always of surgery, either. In the hands of the physiologist, animal experimentation has led to some of the great discoveries, but only when a thorough knowledge of comparative physiology enabled the experimenter to properly appreciate how much the results of experiments on animals could be applied to human beings, and how much was utterly inapplicable. Even in the hands of professed physiologists it has been the source of a good deal of error, because it was often unwarrantably assumed that observations made on animals would hold good in men.

In the recent rapid progress of medicine the quest for the new has led workers in all departments into the apparently rich field of animal experimentation. Discoveries of drug effects seemed easy, and organic changes of the most varied kinds were artificially produced, and then their mode of origin suggested as the explanation of analogous processes in human beings. With usually no knowledge of comparative physiology to guide them, and too often the spirit of acquiring cheap notoriety to urge them to publication, it is no wonder that animal experimentation, except under proper safeguards, is coming into disrepute. This state of affairs is unfortunate, because it constitutes the best argument of the antivivisectionists, though the abuses which have crept in can in no way lessen the value of the great discoveries which physiologists have made by the proper use of vivisection.

Professor Von Jaksch, in his latest work on "Intoxications," in Nothnagel's Series, takes care to say that none of his conclusions are founded on observations made on animals, and within this last month or two I have heard at least three university medical professors decry the invasion by animal experimentation of so-called clinical medicine. A prominent journal of "Clinical Medicine" (*sic*) here in Germany, within the last couple of months published an ordinary-sized number of 150 pages, containing three articles with the following titles: "Physical and Chemical Examinations of the Osmotic Pressure of Animal Fluids," "The Law of the Excentric Position of the Long Tracts in the Spinal Cord," and "The Effects of Thyroid Preparations on the Animal Organism." If at some future day such a journal is to be taken as an index of the interests of clinicians in our day, verily, it will be thought that the rich field of clinical, *i. e.*, bed-side observation, had been abandoned for the fantastic theorizing or seductive illusions of animal experimentation.

Dr. Röse of Munich found in examining recruits that the state of preservation of the teeth seemed to depend to a great extent on the salts in solution in the drinking-water of the part of the country from which they came. Most of the recruits who came for examination were from the country districts, so that a good many of the factors that lead to early decay of the teeth in cities—the sudden change from hot to artifically cold foods and drinks, from the very sweet to the very acid, and, in general, the excessive consumption of sweets and acids could be eliminated. He thought that under these circumstances he could set it down as a general law that, the harder the water of a district, *i. e.*, the more calcium and magnesium salts it contains in solution the better the teeth of the inhabitants; while, on the contrary, the softer the water, *i. e.*, the more free from these salts, the worse the teeth. Dr. Röse thought that he could tell from the color of the inhabitants' teeth how much lime there was in the water of the neighborhood they lived in.

This generalization was not readily accepted. It was pointed out that too few observations had been made to admit of any widely applicable conclusion. There comes now from Sweden a rather startling confirmation of it. Swedish dentists, from the statistics of some 2000 patients from all over the country, collected by Förberg, agree that the rule is a true one, and that the preservation of the teeth depends on the lime salts in the drinking-water. If so, it is probable that other bony structures are subject to the same influence, in which case observation may lead to some important influences as to fracture idiosyn-

crasies and certain other conditions of the bony skeleton of which little is known.

Landry's paralysis, acute ascending paralysis as it has also been known, is at present, it would seem, in an eclipse. Whether it will ever emerge from the darkness again remains to be seen. Neurologists and clinicians all speak of it in a very dubious way, and many of them deny its independent existence. The symptom complex under which it masqueraded for a time is now known to belong more properly to a peripheral neuritis, beginning at the ends of the extremities and gradually invading larger and larger nerve trunks. It is said that all the cases of so-called Landry's paralysis may be included under this head, and cases of the disease in which the peripheral nerves were examined always showed neuritic changes. As to the other pathologic alterations found in the nervous system after death from the disease, they are too varied, too little connected with one another, and too often contradictory of one another to furnish a genuine pathologic basis for an independent disease.

PREVENTION OF DEATH FROM AIR-EMBOLISM — MARKED LEUCOCYTOSIS IN INFANTILE PERTUSSIS—THE BACILLUS OF RHEUMATISM—RESTITUTION OF THE MUCOUS MEMBRANE OF THE URETER AND BLADDER—ANGINA DUE TO STREPTOCOCCIC INFECTION AND FOLLOWED BY POPLITEAL PHLEBITIS.

AT the session of the Biological Society, January 22d, BEGOUIN spoke of the *asphyxia which follows the introduction of air into the jugular vein*, and of the means which may be employed to prevent death under such circumstances. Death is due to the accumulation of air in the right ventricle, and in rabbits and dogs artificially asphyxiated by air blown into their veins, Begouin was successful in saving life by puncturing the right ventricle with a fine, hollow needle, and aspirating the contained air. He believes that the same treatment will be followed by success in operative accidents of this character.

MEUNIER called attention to the very *marked degree of leucocytosis which exists in infantile whooping-cough*, a degree far in excess of that which accompanies other respiratory troubles. This leucocytosis appears early, before the characteristic spasms of coughing come on. The maximum, according to the blood-count in several cases, averages 30,000 white cells per cubic millimeter. The increase in white globules depends upon the lymphocytes, so that the proportion between them and the polynucleated leucocytes is inverted. Intermediate forms and eosinophiles are only slightly altered in number. This variation in the constitution of the blood is difficult to explain. It may perhaps be due to the extreme congestion of the bronchial and tracheal glands which occurs in whooping-cough.

At the session of January 29th, TRIBOULET showed the heart of a rabbit which died twenty days after inoculation with a culture of *coccobacilli obtained from the blood of a patient suffering from acute articular rheumatism*. This rabbit's heart showed typical lesions of rheumatic endocarditis, and in the veins of the mitral valve were found diplococci. There was, moreover, a thickening of the pericardial and pleural membranes, though the serous membranes of the abdomen and of the joints were absolutely unaffected. Pure cultures of coccobacilli were obtained from the blood and principal organs. Although these organisms have been found in the blood of several rheumatic patients their rôle in this disease is not absolutely determined, and the rabbit in question cannot properly be said to have had rheumatism, inasmuch as the joints were not affected.

APERT placed small quantities of blood from two patients suffering with chorea and endocarditis in tubes of anaerobic milk. One culture remained sterile; in the other, a diplococcus developed similar to that described as occurring in rheumatism.

At the Academy of Medicine, February 1st, CORNIL read a paper upon the *restitution of the mucous membrane of the ureter and bladder* after experimental incisions made in dogs. In the first animals experimented upon a ligature was placed upon the ureter, with a fistula above it, and the bladder was sutured so as to divide it into a right and left portion. The lower portion of the ureter and one-half of the bladder were thus kept free from contact with the urine. Incisions in these portions of the bladder and ureter healed perfectly even though left without suture. In another dog the upper portion of the bladder was removed, and the large omentum stitched to the cut edges so as to complete the walls of the viscus. It united without difficulty besides forming anteriorly very close adhesions to the abdominal wall, thus in a measure restoring the portion of the bladder which had been removed.

At the Medical Society of the Hospitals, January 28th, TROISIER mentioned a case of *angina due to streptococci* in a young man. A week after recovery he was seized with pain in the right leg, and again entered the hospital. He presented the symptoms of *phlebitis in the popliteal region*. This complication disappeared within about two weeks. It was concluded that an infection from the tonsil had entered the blood and set up this phlebitis. A culture made from the blood on the third day after the appearance of phlebitic symptoms remained sterile. This was, however, rather late in the course of the disease to expect to find organisms in the blood, and, moreover, streptococci are demonstrated in the blood with difficulty, even in cases of severe infection.

Vienna.

REMOVAL OF SYPHILITIC GUMMA OF THE BRAIN—RUPTURE OF THE BICEPS TENDON—BRONCHITIS WITH CONCRETIONS—USE OF LEAD PLATES TO FACILITATE THE LOCATION OF FOREIGN BODIES IN THE HEAD BY MEANS OF ROENTGEN-RAYS—ATYPICAL FORMS OF ACUTE RHEUMATISM—A CASE OF CHRONIC TETANUS—A DISCUSSION ON CHLOROSIS.

At the session of the Imperial Royal Society of Physicians of January 21st, SCHLESINGER described a case of *gumma of the cortex of the brain which had been*

successfully removed. The patient had been subjected to energetic treatment with mercury and the iodids, but, nevertheless, pain and paralysis increased, and operation was, therefore, determined upon. Before operation there was paresthesia of the right side of the tongue, of the right cheek, and finally of the right upper, and later of the right lower extremity. The tumor was found to be situated partly in the anterior central, and partly in the posterior central convolution, and had a diameter of more than one inch. It was caseous and was removed without much difficulty, leaving a cavity about one-half inch in depth. The paralysis rapidly disappeared and the ability to speak was almost wholly regained within ten weeks. Schlesinger thinks that an operation of this character is indicated in those patients in whom the lesion is cortical and circumscribed, and whose symptoms are increasing in spite of antisyphilitic treatment.

At the session of January 28th, VON HOFMANN presented a male patient aged twenty-eight years who *ruptured the long biceps tendon* a year and a half previously without any serious loss of function. The typical symptoms of rupture were present, *viz.*, a depression above the belly of the biceps, an unusually marked swelling of the latter, which was also abnormally near the ulna.

MAGER exhibited a woman who, after recovery from a severe attack of pneumonia, suffered from *violent attacks of coughing*, lasting for hours, and associated *with expectoration of small concretions* covered with mucus and occasional specks of blood. Altogether about thirty such concretions had been coughed up. They consisted of calcium phosphate and calcium and magnesium carbonate. Tubercle bacilli had never been found in the sputum and the physical examination of the lungs was negative.

STOCKL described two cases in which *foreign bodies* in the head were *located with exactness by the use of the Röntgen-rays facilitated by covering portions of the head with lead plates* in order to bring out more sharply the density of the different shadows.

SINGER spoke at the session of the Medical Club of January 19th, upon *atypical forms of acute rheumatic arthritis.* Typical rheumatism is characterized by swelling of the joints and disorders of the skin, heart, and of the serous membranes, which are favorably influenced by salicylates. In 1885, Immermann called attention to certain cases of neuralgia of the trigeminus beginning with fever and accompanied with swelling of the joints and heart symptoms and which were favorably influenced by salicylates. Edlefsen called this an embryonic form of polyarthritis, and to-day we include in it certain cases of sciatica. That chorea is to be classed among the atypical forms of rheumatism is shown by the symptoms in the joints and endocardium as well as by certain bacteriologic discoveries. Moreover, polyneuritis has much in common with polyarthritis, which it often follows. The post-rheumatic muscular atrophies which owe their existence to polyneuritis must also be included in this classification. Herpes labialis and herpes zoster may also be considered, as atypical manifestations of rheumatis m. Therefore the joint symptoms should be regarded as the most striking rather than the most universal manifestations of rheumatism. The most reliable symptom is fever, which is common to all forms and often extends beyond the period in which there are symptoms in the joints. The etiology of the disease lies in an infection of the blood.

PINS thought Singer went too far in describing rheumatism as an infection of the blood. The fever could be explained by an inflammation of the vessels of some particular organ.

At the session of January 26th, PINELES described *a case of chronic tetanus.* Twenty years ago the patient, at that time a girl of seventeen years, passed through a severe attack of typhoid fever which terminated in painful contractions, taking the form of tetanus. Every year since that time the tetanus recurred during the months of January, February, or March. During the last fourteen years there had been a disturbance of the stomach and intestines, manifesting itself at different periods of the year, often in the form of a persistent diarrhea. The tetanic symptoms, however, occurred during the months mentioned.
